A case can be made that the personality variables self-esteem and locus of control play a central role in the evaluation of many situations and thus contribute to the experience of stress. Self-esteem is broadly defined as the value we place on ourselves. Epidemiological studies have shown that low self-esteem is associated with negative life outcomes, including substance abuse, delinquency, unhappiness, depression, and worsened recovery after illnesses. On the other hand, high self-esteem has been linked to happiness and longevity. In studies of aging, a positive self-concept has been identified to play a key role in successful aging, predicting independence, cognitive stability, and general health in old age.

Internal locus of control can be defined as the perception that one's outcomes are determined by one's actions. Not surprisingly, internal locus of control and self-esteem are usually highly correlated. The key link of these variables to the experience of stress lies in their impact on the evaluation of any given situation. We postulate that in the evaluation of whether a given situation is threatening or benign, self-esteem and internal locus of control systematically interact with situational factors. If a person attributes little importance to him- or herself and thinks that he or she has little impact on the outcome of his or her own actions, this person will find more situations uncontrollable and unpredictable, and consequently will evaluate more situations as threatening and harmful.

Endocrinological Evidence for the Role of Self-esteem and Locus of Control in the Perception of Stress

Evidence for the impact of self-esteem and locus of control on stress perception emerged when subjects were exposed to repeated psychological stress, using the Trier Psychosocial Stress Test (TSST). In this paradigm, subjects have to give an impromptu speech and perform serial subtraction tasks in front of an audience, usually for about 10 min. The audience consists of two to three persons who are instructed to maintain a neutral expression, being neither explicitly rejecting nor confirmative in their facial expression or gestures. During the speech, the audience interacts with the subject only to indicate the amount of time that is left to talk or to ask specific questions.

In the case that a subject stumbles, they encourage the subject to continue the speech. During the serial subtraction task, the subject is interrupted only when making a mistake. The subject is then corrected and instructed to start the task over. The task was designed to represent a significant social-evaluative threat and indeed has been shown to be a powerful stressor, stimulating the hypothalamic-pituitary-adrenal (HPA) axis and leading to significant free cortisol increases within 15 to 30 min following the onset of the task. This first study aimed to validate the long-standing hypothesis that in humans, repeated exposure to the same stressor would lead to quick habituation of the stress response. In order to test the habituation of the stress response, 20 young healthy male college students were exposed to the TSST on five subsequent days. For this purpose, the TSST was modified using different speech topics and serial subtraction tasks on each day. Interestingly, only 13 of the 20 subjects showed the typical habituation pattern, with a normal stress response on day one being significantly reduced on day two, and no longer present on the subsequent days. In the seven remaining subjects, however, the cortisol stress response continued to be present on all days and only showed a tendency to decline toward the end of the testing (Figure 1). When analyzing the available psychological variables, it became apparent that low internal locus of control and low self-esteem were the best predictors of failing habituation of the cortisol stress response to repeated stress exposure. This can be interpreted as a sign that these personality variables interact with the evaluation of a situation during repeated exposure. The absence of differences in the stress response between the two groups of subjects on day one was at the time attributed to the effect of

novelty – the novelty of the situation might have made it unpredictable and uncontrollable for everybody on the first exposure and might thus have masked the impact of personality variables on stress perception and response. One conclusion at the time was that in order to reveal the effect of personality variables on the stress evaluation and response, one would likely need repeated exposures to the same stressor in order to reveal the influence of personality variables on stress.

However, it is known that personality variables tend to have relatively weaker effects when situational factors are very strong. In a second study, the threatening aspects of the situation were reduced, and self-esteem and locus of control had an impact on the perception of stress on the first exposure to a stimulus. Here, computerized mental arithmetic was combined with an induced failure design to invoke stress. In the setup used in this task, 52 students performed the task on computer terminals in front of them. Half of the students were exposed to a difficult version leading to low performance, compared to an easy version of the task with high performance for the other half. The students played the task in three 3-min segments and had to announce their performance score after each segment to the investigator, who wrote the scores down on a board for everybody to see. Saliva sampling before, throughout, and after the task allowed the assessment of the cortisol dynamics in relation to this paradigm. Interestingly, this task triggered a significant cortisol release only in the subjects who were in the low-performance group and had low self-esteem and low internal locus of control. Neither low performance alone nor low self-esteem and internal locus of control alone were significant predictors of cortisol

Figure 1 Cortisol responses (AUC, area under the curve) on repeated exposure to the Trier Social Stress Test (TSST) on 5 subsequent days in subjects with high self-esteem and high locus of control (high SEC; $n = 13$) and low self-esteem and low locus of control (low SEC; $n = 7$).

Figure 2 Cortisol stress responses to the Trier Mental Challenge Task (TMCT) in four groups of subjects, separated for high and low self-esteem and locus of control and high and low performance in the mental arithmetic. The performance was manipulated by the investigator.

release, supporting the notion that these personality variables produce effects only in interaction with a potentially stressful situation (Figure 2). The evaluation of the situation is suggested to be at the core of this interaction.

The Hippocampus as a Possible Mediator of the Relationship between Self-esteem, Locus of Control, and Stress

Although studies on brain correlates of personality variables and endocrine function in humans are only starting to appear, a picture is emerging that puts the spotlight on the hippocampus as a likely mediator between the previously reported personality variations and stress responses. The hippocampus is one of the major limbic system structures involved in the regulation of the stress response, and variations in hippocampal volume (HCV) have been postulated and shown to be systematically linked to excessive HPA axis activity. Early models postulated that associations between HCV and HPA axis activity might represent the consequence of excessive exposure of the hippocampus to glucocorticoids, due to their powerful neurotoxic properties.

More recently, however, evidence for a link between naturally occurring variations in HCV and HPA function has surfaced. Functionally, the hippocampus is the primary structure for memory contextualization, and it is here that a link to self-esteem and locus of control could occur. When an individual is

faced with a potentially threatening and harmful situation, he or she employs memories of past events to contribute to the evaluation of the current event. However, if specific situational and environmental characteristics associated with negative past events cannot be recalled, this lack of awareness of situational circumstance can lead to an overgeneralization of negative past events and thus an increased likelihood to consider the current situations as stressful as well. Thus, poor contextualization mediated by the hippocampus could be linked to higher stress responses, on the one hand, and lower self-esteem on the other.

This hypothesis of a link between HCV, personality variables, and stress responses was tested in 17 healthy young male college students. All subjects underwent extensive psychological assessment for assessment of personality variables, including self-esteem and locus of control. In addition, they underwent magnetic resonance imaging employing a structural T1-weighted acquisition protocol, which produces high-resolution images of the cerebrum. A recently developed manual segmentation protocol was then applied to all images that included nonuniformity correction, signal intensity normalization, and Talairach-like transformation for standardization of brain size. This protocol allows for manual assessment of hippocampal volumes. Finally, all subjects were exposed to a computerized stress task, similar to the mental arithmetic task described earlier. Saliva samples before, during, and after the task accompanied the testing to capture the cortisol stress response. Results first replicated earlier findings of mental arithmetic stress: only the subjects with low self-esteem and low internal locus of control showed a significant release of cortisol. Extending earlier findings, however, a correlation emerged between the cortisol stress response and self-esteem ($r = -0.45$, $p < 0.05$). Furthermore, a significant correlation emerged between the cortisol stress response and the total hippocampal volume ($r = -0.53$, $p = 0.03$), suggesting that the size of the hippocampus is related to the regulation of the HPA (Figure 3a). Finally, supporting the initial hypothesis, a link was observed between internal locus of control and HCV ($r = 0.66$, $p = 0.006$; Figure 3b) and self-esteem and HCV ($r = 0.58$, $p = 0.02$; Figure 3c).

Testing for the specificity of the effect with regard to the hippocampus, total brain gray matter was employed as control structure in correlations with both personality variables and cortisol response. None of the tested correlations were significant, suggesting that the observed relationships were indeed specific to this medial temporal lobe area.

Figure 3 Correlation between hippocampal volume and cortisol stress responses to a mental arithmetic task (a), hippocampal volume and locus of control (b), and hippocampal volume and self-esteem (c) in a group of 17 healthy young male college students.

Conclusion: Personality Variables, Brain Structures, and Stress Responses in a Developmental Context

It will be a challenging task for future studies to ascertain the origin of the relationship observed between personality variables, hippocampal volume, and stress response. There are a number of possibilities as to how these associations could develop. One

model puts naturally occurring variations in hippocampal volume at the origin of these functional relationships. It can be speculated that HCV is a consequence of multiple interacting factors during critical developmental stages, leading to the variation in HCV that follows a normal distribution pattern. If, however, the size of this structure determines memory contextualization capabilities, this variation would then have personality and stress-related consequences. The impaired source monitoring would lead to an overgeneralization of the experience of failure and rejection, and consequently to a self-perception of being a failure or being socially rejected in general, which might produce low self-esteem and low locus of control during childhood and adolescence. The observed higher cortisol responses would then not be a direct consequence of small HCV, but of the increased stress perception due to consistent unfavorable evaluations of ambiguous situations. Of course, the question arises why overgeneralization should then not also be an issue for positive life events, in other words, a general lack of source monitoring for both positive and negative life events with no consequences on self-perception. One possible explanation could be seen in the stress-specific function of the hippocampus within the limbic system. There is evidence that it is specifically the hippocampus together with the anterior cingulate that is involved in the stress response. It is also known that the anterior cingulate is particularly involved in error monitoring, which means that its involvement is restricted to situations in which a mismatch between expectations and reality occurs. These circumstances would make a specific role of the hippocampus in reaction to negative life events more probable.

Based on the findings to date, we suggest that reduced HCV might play a role in the development of low self-esteem. This may in turn produce a higher susceptibility of perceiving ambiguous situations as threatening, and thus stressful. The idea that HCV variation might be the cause for adverse functional and behavioral consequences, rather than their consequence, has recently been proposed in conjunction with risk factors for developing posttraumatic stress disorder (PTSD) in a study investigating hippocampal volume in twin brothers. Here, in subjects who developed PTSD as a consequence of participating in the Vietnam War, the researchers observed lower hippocampal volume compared to subjects who went to war but did not develop PTSD. Intriguingly, however, lower hippocampal volume could also be observed in the PTSD subjects' twin brothers – who never went to war – leading to the speculation that HCV might be a risk factor for, rather than a consequence of, developing PTSD.

As mentioned earlier, the possibility that HCV plays a causal role is supported by the fact that consistent results were found even among relatively young adults. Recently, variations in HCV in young populations have been reported, suggesting that there is a considerable range of hippocampal volumes already in young subjects. At the same time, self-esteem is known to be a stable trait, with considerable intra-individual stability throughout life. This supports a model in which variations in brain morphology could become a pathway to certain personality characteristics and behavioral phenotypes early in life, but longitudinal studies will be needed to examine these changes over time and provide validation for the assumed associations.

Glossary

<i>Allostasis</i>	The ability to reestablish homeostasis through change during adaptation to stress.
<i>Allostatic load</i>	The cost of allostasis; a too high cost may lead to wear and tear, and ultimately to disease.
<i>Corticotropin releasing hormone (CRH)</i>	A hormone produced in the hypothalamus that stimulates after secretion in the portal vessels the release of pituitary ACTH.
<i>Homeostasis</i>	A stable <i>milieu intérieur</i> , which refers to the defense of physiological and psychological integrity.
<i>Homeostatic mechanism</i>	The processes and activities coordinated by the stress system that help to maintain homeostasis.
<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	Refers to a coordinate pattern of stimulation and feedback interaction between hypothalamic paraventricular neurons, pituitary corticotrophs and the adrenal cortex with the aim to facilitate adaptation to stress and to synchronize daily and sleep-related events.
<i>Nuclear receptors</i>	Proteins that bind steroid hormones and that can act in the cell nucleus as gene transcription factors in the modulation of gene expression. The receptors appeared recently to reside also in the membrane where they mediate fast non-genomic actions. In the brain, mineralocorticoid receptors are promiscuous and bind with high affinity naturally occurring glucocorticoids (cortisol and corticosterone), mineralocorticoids, and progesterone; glucocorticoid receptors

Stress system balance hypothesis

Stress system mediators

Stress response

bind exclusively naturally occurring and synthetic glucocorticoids.

The characteristic of a stress system that rapidly turns on and off.

Substances that stimulate the endocrine system to secrete hormones; here used to indicate the peptides released by hypothalamic neurons in the pituitary portal vessel system.

The set level of the regulated variable (physiological function); homeostatic mechanisms serve to restore the set point perturbed by stress. Allostasis reflects an adaptive change in the set point necessary to cope with the stress.

Any perceived threat to the individual's integrity.

The hypothesis that the defense of homeostasis and development of allostasis depend on the balanced interaction between activating and inhibiting humoral and neural stress system mediators.

The network of humoral and nervous mediators of the stress response.

The spectrum of physiological and behavioral adaptations that defend homeostasis and/or to achieve allostasis and that are coordinated by the stress system mediators.

A stressor is any real or perceived threat to homeostasis (i.e., the stability and integrity of the organism). The defense of homeostasis to the stressor triggers a corrective physiological and behavioral response (the stress response) that is coordinated by humoral and nervous mediators, the stress system mediators. In particular, psychological components of the stress response often require adaptation to the stressor through change, a process termed allostasis. The stress-induced activation and termination of the action of the mediators in humoral and nervous signaling represent two compensatory phases: some mediators act in an opposing mode and others in a synergistic mode (Table 1). The two modes of stress system operation need to be in balance, however, to ensure a proportionate outcome in the third and preparative phase for the next stress response. This implies the storage of the experience in memory and the storage of energy resources for coping with future needs. A disproportionate outcome of stress system operation has been termed allostatic load and is considered an unfavorable prediction for health.

Table 1 Some selected mediators of the two modes of stress system operation^a

<i>Activating mode: fight-flight-fright</i>	<i>Suppressing mode: coping and adaptation</i>
CRH, CRH-1 receptors	Urocortins, CRH-2 receptors
Vasopressin	Oxytocin
ACTH	Endorphins
Sympathetic response	Parasympathetic response
Mineralocorticoid receptors	Glucocorticoid receptors

^aThe two modes are in balance for homeostasis and health. ACTH, adrenocorticotrophic hormone; CRH, corticotropin releasing hormone.

Such a disproportionate outcome is reflected in an increased vulnerability to stress-related diseases. In the brain, such diseases are characterized by emotional lability and cognitive disturbance. Both may have profound consequences for metabolic, immune, and cardiovascular regulations.

Corticotropin Releasing Hormone and Urocortins

Most mediators of the stress system are known and their molecular and anatomical organization is being unraveled. Hierarchically, the hypothalamic paraventricular nucleus (PVN) integrates all stressful information. The PVN is activated directly by physical stressors through aminergic ascending pathways and by metabolic disturbance through peptidergic hypothalamic pathways. Psychologically stressful information is conveyed transsynaptically to the PVN after limbic-midbrain processing. The PVN contains different cell types that express peptidergic secretagogues and that, because of their projection to different targets, can activate distinct functions in a coordinate manner.

Hence, the PVN is the organizer of the immediate behavioral, autonomic, and neuroendocrine response to a stressor. The ratio of PVN secretagogues can change as a function of the nervous input. Corticotropin releasing hormone (CRH) is released in changing ratios with vasopressin and other peptides driving the sympathetic and behavioral fight-flight-fright response. The CRH-1 receptors mediating this response can also activate the hypothalamic-pituitary-adrenal (HPA) axis, leading to the secretion of adrenal corticosteroids. To achieve this goal, CRH and vasopressin are secreted in the pituitary portal vessel system and induce in the anterior pituitary the synthesis of proopiomelanocortin (POMC), which is processed to balanced concentrations of adrenocorticotrophic hormone (ACTH), opioids, and melanocortin peptides, for example. ACTH stimulates the adrenal

cortex to secrete cortisol (humans) and corticosterone (humans, rats, and mice), whereas opioids attenuate stress reactions, resulting in suppression of adrenal function. Collectively, these mediators of the HPA axis act in concert to coordinate the neuroendocrine stress response. The mechanism underlying the CRH-induced sympathetic outflow and behavioral response pattern is not precisely known.

Recently, urocortin II and III (stresscopin and stresscopin-related peptide, respectively) were identified acting through the CRH-2 receptor system. The CRH-1 and CRH-2 receptor systems have a partly overlapping distribution in the brain, which matches their CRH and urocortin terminal fields. The intracerebroventricular administration of CRH mimics the initial behavioral, autonomic, and neuroendocrine stress response and is anxiogenic. In contrast, urocortin seems to have opposing functions as expressed, for example, in its anxiolytic properties. It is well established that the CRH/CRH-1 receptor system organizes the onset of the stress response.

Some investigators have proposed that the urocortin-CRH-2 receptor system represents a slower mode of operation of the stress system mediators, perhaps one that is primarily concerned with adaptation and coping with stressors. Such a bimodal CRH-1/CRH-2 receptor-driven neuroendocrine system would control over time the compensatory phases of initiation and termination in the stress response. Such a system would operate in an integrative fashion with the sympathetic and parasympathetic divisions of the autonomic nervous system, and the signals released from the dendritic cell would control the balance between immune activation and tolerance. In fact, other neuropeptides in the stress system, such as vasopressin and oxytocin, also have opposing actions in aspects of behavioral adaptation.

Glucocorticoids

The importance of a balance in the concentration and action of stress mediators is illustrated also by the glucocorticoid hormone (cortisol or corticosterone) secreted from the adrenal cortex. The hormone operates both in the fast and slow modes of the response to stress and produces lasting effects in the preparation of future events. In concert with the other stress mediators, the hormone has two modes of operation that are complementary. First, it acts permissively and exerts a tonic influence on cellular and tissue functions. In the behavioral realm, the hormone operates in a pro-active mode, so that the organism is prepared in anticipation of upcoming events. Second, once homeostasis is disturbed, the concentration of cortisol rises in response to HPA axis activation to

promote the recovery of disturbed homeostasis. High concentrations of cortisol operate in a reactive mode, through feedback foremost, by preventing the initial stress reactions from overshooting and to become damaging in themselves.

The two complementary modes of operation of cortisol depend on the concentration of the hormone, the context and the phase of the stress response. In the low basal mode pro-active hormone actions seemingly have a household function in which the hourly pulses of the hormone over the circadian cycle provide the capability to synchronize upcoming daily and sleep-related events and to coordinate the available mental and body resources to deal with upcoming challenges. These functions are stepped up when cortisol levels rise in the stress mode. At the same time, the redistribution of resources is facilitated, enabling the individual to cope and to suppress any overreaction to a stressor in the reactive mode. Cortisol action operating in the basal and the stress mode therefore displays an enormous diversity in action that is dependent on the context. The context is a reflection of the signals provided by the other local and systemic stress mediators that converge in time and phase in the cell or tissue in which homeostasis has been challenged. In other words, it is essential that the hormones act in the right time window on the cells and circuits in the brain that have initially led to their own secretion. If they act out of context, the hormones' action becomes damaging.

Two Corticosteroid Receptor Types: Low and High Levels of Stress System Operation

The molecular basis of the dual mode of operation of cortisol is formed by two types of receptors – mineralocorticoid receptors (MRs) and glucocorticoid receptors (GRs) – that bind *in vivo* cortisol with an order of magnitude difference in affinity. However, this only occurs if the cells lack 11 β -hydroxysteroid dehydrogenase type 2 (11 β -HSD2), which inactivates the steroid. The receptors have a different distribution. GRs occur in virtually every cell and are expressed most abundantly in cells with a key role in coping with stress (e.g., the liver, immune system, and limbic forebrain regions). The cortisol-responsive MRs are expressed abundantly in the heart, vascular tissue, and limbic-forebrain regions such as the hippocampus. Using selective antagonists and conditional knockout strategies, researchers have studied their functions in experimental animals from gene to behavior.

MRs and GRs are nuclear receptors that mediate the slow genomic actions of cortisol. The receptors

recruit patterns of coregulators and transcription factors to facilitate their dual mode of operation. In cellular studies using the hippocampus, cortisol suppresses through MR inhibitory inputs and Ca influx. The consequence is that excitatory transmission is facilitated, and Ca²⁺ availability is suppressed, which is a favorable condition for a cell. MR activation indeed protects against damage caused by ischemic insults and suppresses apoptotic pathways.

GRs are occupied in the ultradian and circadian peaks of circulating cortisol. GRs are also occupied after stress-induced rises in cortisol; thus, in hippocampal neurons, the activation of GRs some time after exposure to the stressor suppresses the stress-induced disturbances in excitability transiently raised by excitatory input. The recovery process promoted by GRs enhances a hyperpolarizing input and Ca²⁺ influx; the latter process, although beneficial in the short run, may explain why chronically elevated high glucocorticoid levels and excitotoxic challenge create unfavorable conditions for the functioning of the hippocampal neurons.

Corticosteroid Receptor Balance

From these cellular studies and from endocrine and behavioral observations, a concept has evolved in which MRs and GRs mediate the dual mode of operation of cortisol in the limbic brain to regulate in a coordinate manner the onset and termination of the response to a stressor. Because limbic areas such as the hippocampus, amygdala, and frontal cortex are the target, the action of cortisol depends on stressful information determined by spatial and temporal cues. MRs are implicated in the appraisal of the situation and in processes involved in the prediction and choice of the appropriate behavioral reaction to deal with a challenge. Such predictive responses are important for the onset of the stress response by determining the threshold or sensitivity of the stress system to challenge. Along the same line of reasoning, MRs are in a proactive mode of operation implicated in predictable ultradian and circadian changes. High levels of cortisol facilitate through GRs the termination of the stress reactions in a reactive fashion, mobilize for this purpose the required energy resources, and facilitate recovery. Due to their occupation during pulsatile and circadian peaks, GRs may function as Zeitgeber. In preparation for future events, GRs promote memory processes and the storage of energy resources. So, the two receptor types belong to interacting signaling networks that underlie adaptive processes from appraisal of novel situations and prediction of upcoming events to recovery from the challenge and storage of the experience.

in memory. They participate in the control of energy metabolism, from appetite and feeding to energy disposition and storage.

Nuclear Receptors: Slow Genomic and Fast Membrane Actions

To this analysis can be added the mechanism of action of steroids in the brain via MRs and GRs. The nuclear receptors are well known as mediating the slow genomic actions of glucocorticoids. Recently it has become evident that these receptors also serve at the membrane level to mediate rapid glucocorticoid actions. A clear example is the fast MR-mediated action of corticosterone and cortisol on the release of the excitatory transmitter glutamate in the hippocampus. These fast steroid actions probably have a function in the pro-active modes of action of the steroid in anticipated perturbances of homeostasis.

Perspectives

Three questions are at the core of stress system operation and health: how is the stress system balance regulated, what are the implications of dysregulation for health and disease, and which biomarkers can reveal a balanced stress system operation?

Regulation of Stress System Balance

Regulation of the stress system balance is by definition based on the activity of the humoral and neural mediators that are activated by stress. In the case of the corticosteroids it depends on their secretion rate; bioavailability; access to the brain through multidrug-resistant P glycoprotein; the stoichiometry of receptors, coregulators and other proteins and genetic factors. Genetic variants and polymorphisms can bias the response patterns. Recently, knowledge of epigenetic control of gene expression and function has grown; it has been demonstrated that stable alterations in stress system mediators may occur as a result of environmental input and early life experience. In later life, psychosocial contexts that challenge the individual's coping ability, particularly if experienced chronically, also cause enduring changes in stress system operation.

Implications for Health and Disease

Stress mediators acting either excessively or inadequately produce a phenotype vulnerable to stress-related disease in predisposed individuals. The causes of aberrant stress system operation can be environmental, experience-related, or genetic; it is reflected in the ability to cope with a stressor, and it is also

affected by additional factors such as life style and diet. It is believed that an imbalance, rather than the absolute concentration of stress system mediators, compromises resilience and enhances vulnerability to disease. This condition has been termed allostatic load.

Selye championed the balance of mineralocorticoid versus glucocorticoid actions as determining pro- versus anti-inflammatory actions. Selye proposed that imbalance therefore enhanced the risk for inflammation or infection. In modern terms, in the brain the action of one single hormone – cortisol or corticosterone – depends on the balance of MR- and GR-mediated actions. Once the balance is disturbed, the individual loses the ability to maintain homeostasis when challenged by an adverse life event. This may lead to a condition of neuroendocrine dysregulation and impaired behavioral adaptation, enhancing the precipitation of stress-related disease for which the individual is genetically predisposed.

Biomarkers

Stress-related diseases, such as depression, are complex and multifactorial diseases. They likely cannot be attributed to mutations in a single gene or to a single external event; instead, they result from the concerted actions of many subtle genetic polymorphisms and from external events, the effects of which might accumulate over time. Once traumatic life events in combination with genetic disposition have engrained long-lasting changes in MR and GR signaling, a vulnerable phenotype emerges. MRs and GRs may therefore be considered as allostatic markers. The individual's vulnerability is defined by three different levels of description: the traditional clinical phenotype (emotional reactivity and personality), the functional phenotype (neuroendocrine reactivity to stimuli, MRs, GRs, and beyond), and the genotype (e.g., polymorphisms in genes that are involved in HPA signaling or monoaminergic neurotransmission). An integrated approach that analyzes patients at all three levels may provide insight into the causes of stress-related diseases and perhaps also into new targets for treatment.

Glossary

Adversarial growth

Increased psychological functioning and personal development following exposure to a stressful and traumatic event; also called posttraumatic growth or stress-related growth.

Assumptive world

Cognitive schemata about the self and world that determine how meaning is perceived.

A number of literatures, religions, and philosophies throughout human history have conveyed the idea that there are benefits to be found in suffering. However, it is only relatively recently that the topic of benefit finding following stress and trauma has become a research focus. Initially there was some debate over the validity of the concept of benefit finding, with some commentators questioning whether it was anything more than positive illusion and self-deception. But there is now convincing evidence that people often experience benefits following stress and trauma. These benefits have been variously labeled adversarial growth, benefit finding, flourishing, heightened existential awareness, perceived benefits, positive by-products, positive changes, positive meaning, post-traumatic growth, quantum change, self-renewal,

stress-related growth, thriving, and transformational coping. These terms have been used interchangeably to refer not just to recovery following stressful and traumatic events but to how events can sometimes serve as a springboard to a higher level of psychological functioning.

Types of Benefit

Three broad interrelated dimensions of benefit finding have been discussed. First, relationships are enhanced in some way; for example, people now value their friends and family more and feel an increased compassion and altruism toward others. Second, people change their views of themselves in some way; for example, they have a greater sense of personal resiliency, wisdom, and strength, perhaps coupled with a greater acceptance of their vulnerabilities and limitations. Third, people report changes in life philosophy; for example, they find a fresh appreciation for each new day and renegotiate what really matters in the full realization that their life is finite, including possibly changing their spiritual beliefs. Various psychometric self-report instruments have been developed with which to assess positive changes and personal growth following adversity: the Changes in Outlook Questionnaire, the Perceived Benefit Scale, the Posttraumatic Growth Inventory, the Stress-Related Growth Scale, and the Thriving Scale. The development of these instruments has led to further empirical investigation.

Prevalence

Prevalence varies among studies due to samples, contexts, and methodological issues, but it is expected that anywhere between 30 and 70% of people may experience some form of benefit following traumatic events, although the benefits are not usually reported in the immediate aftermath but at some later time. Also, the benefits are likely to coexist with psychological distress; the experience of benefits is not mutually exclusive with other more negative psychological consequences.

Etiological Factors

Studies have reported benefits following a range of stressful and traumatic events, for example, bereavements; accidents and disasters; chronic and life-threatening illnesses; sexual, physical, and emotional abuse in childhood; sexual assaults; and wars and conflicts. Research has also begun to document the correlates and predictors of growth, with evidence pointing to the importance of stress-appraisal, coping, and personality variables, with the more

optimistic, self-efficacious, extraverted, and stable people, who use more spiritual, accepting, emotionally expressive, and emotionally focused forms of coping, being more likely to report benefits. Social support is thought to be important too.

Theoretical Developments

Tedeschi and Calhoun's functional-descriptive model shows how traumatic events serve as seismic challenges to the pretrauma schema by shattering prior goals, beliefs, and ways of managing emotional distress. When these schemas are shattered in this way, this leads to ruminative activity as people try to make sense of what has happened and to deal with their emotional reactions to the trauma. In the initial stages, this ruminative activity is more automatic than deliberate. Although distressing, automatic ruminative activity is indicative of cognitive activity that is directed at rebuilding the pretrauma schema. This ruminative process is influenced by social support networks, which provide sources of comfort and relief, as well as being influenced by new coping behaviors and available options for the construction of new posttrauma schemas. Successful coping at this stage facilitates disengagement from goals that are now unreachable and from beliefs that are no longer tenable in the posttrauma environment, together with decreased emotional distress. As successful coping aids adaptation, the initial ruminative activity that was characterized by its automatic nature shifts toward a more effortful ruminative activity. This effortful ruminative activity is characterized by narrative development, part of which may be the search for meaning.

Introducing a metatheoretical perspective, Joseph and Linley proposed that human beings are active, growth-oriented organisms. The theory proposes that individuals are intrinsically motivated to cognitively accommodate their psychological experiences and thus find benefit. The confrontation with a stressful and traumatic event has a shattering effect on the person's assumptive world. When the social environment is able to provide for the basic human needs of autonomy, competence, and relatedness, then models of the self and world transform to accommodate the new trauma-related information. When the social environment does not provide support for these basic human needs, the process of accommodation is thwarted and benefits are less likely to be experienced.

Similarly, but from a biopsychosocial-evolutionary perspective, Christopher regarded growth, rather than pathology, as the normal outcome of the traumatic stress response. Reviewing and synthesizing the trauma literature, Christopher articulated seven interconnected theoretical conclusions:

1. Stress is best understood as a prerational form of biopsychological feedback.
2. The normal outcome of traumatic stress is growth.
3. Any resultant psychopathology is a function of a maladaptive modulation of the stress response.
4. Trauma transforms individuals on the biological as well as psychological levels.
5. Biological processes underlying stress response are universal, but there are specific dynamics that are a function of the individual.
6. Biological changes can occur even if there are no psychological changes.
7. Rationality is humanity's evolutionary newest and most sophisticated stress-reduction mechanism.

Clinical Applications

The interest in benefit finding can be seen as part of the wider positive psychology movement. Positive psychology is seen as a balance to mainstream psychology, which has been for too long overly concerned with the negative aspects of human experience. Research in positive psychology is now beginning to focus on its applications, and the study of benefit finding promises to have important applications for clinical, counseling, and health psychologists, who when working with clients who have experienced stressful and traumatic events need not be concerned only with helping to alleviate distress but also with helping to facilitate more positive functioning.

The importance of this avenue of investigation is seen in the seminal work of Affleck and colleagues, who found that perceived benefits at 7 weeks following a heart attack significantly predicted less chance of heart attack recurrence and lower general health morbidity at an 8-year follow-up. Experimental studies to test whether the principles of growth might somehow be introduced as part of a clinical intervention are encouraging. For example, Stanton and colleagues randomly assigned breast cancer patients to one of two groups, one group to write about the facts of the cancer experience and the other to write about positive thoughts and feelings regarding the experience. It was found that those assigned to write about their positive experiences had significantly fewer medical appointments for cancer-related morbidities 3 months later.

Clinicians should be aware of the potential for positive change in their clients following stress and trauma. But it must also be recognized that adversity does not lead to positive change for everyone. Therefore, therapists need to be careful not to inadvertently imply that patients have in some way failed by not making more of their experience or that

there is anything inherently positive in their experiences. Personal growth after trauma should be viewed as originating not from the event, but from within the patients themselves through the process of their struggle with the event and its aftermath.

Stress involves a stressor and a stress response. A stressor may be a physical insult, such as trauma or injury, or physical exertion, particularly when the body is being forced to operate beyond its capacity. Other physical stressors include noise, overcrowding, and excessive heat or cold. Stressors also include primarily psychological experiences such as time-pressured tasks, interpersonal conflict, unexpected events, frustration, isolation, and traumatic life events, and all of these types of stressors may produce behavioral responses and evoke physiological consequences such as increased blood pressure, elevated heart rate, increased cortisol levels, impaired cognitive function, and altered metabolism.

Behavioral responses to stressors may decrease risk and get the individual out of trouble or involve health-promoting activities such as a good diet and regular exercise, but they may also include responses that exacerbate the physiological consequences of stress such as self-damaging behaviors (e.g., smoking, drinking, overeating, or consuming a rich diet) and risk-taking behaviors (e.g., driving an automobile recklessly). The physiological stress responses include primarily the activation of the autonomic nervous system and the hypothalamic-pituitary-adrenal (HPA) axis, leading to increased blood and tissue levels of catecholamines and glucocorticoids. It is these physiological responses that have both protective and damaging effects (see **Allostasis and Allostatic Load**).

There are two important features of the physiological stress response. The first is turning it on in amounts that are adequate to the challenge (see **Allostasis and Allostatic Load**). The second is turning off the response

when it is no longer needed. The physiological mediators of the stress response, namely, the catecholamines of the sympathetic nervous system and the glucocorticoids from the adrenal cortex, initiate cellular events that promote adaptive changes in cells and tissues throughout the body, which in turn protect the organism and promote survival. However, too much stress or inefficient operation of the acute responses to stress can cause wear and tear and exacerbate disease processes.

There are enormous individual differences in interpreting and responding to what is stressful, as well as individual differences in the susceptibility to diseases, in which stress may play a role. Genetic predispositions exist that increase the risk of certain disorders. In addition, developmental process, such as prenatal stress or nurturing postnatal experiences, contribute to the life-long responsiveness of the behavioral and physiological responses to stressors. Furthermore, experiences throughout the life course that result in memories of particularly unpleasant or pleasant situations combine with the genetic and developmental influences to produce large differences among individuals in how they react to stress and what the long-term consequences may be.

The Stress Response

Depression and Diabetes

Stressful Life Events and Diabetes

Inflammation and Diabetes

Conclusion

Glossary

<i>Adipokines</i>	Cytokine-like molecules produced and secreted by the adipose tissue (e.g., leptin, adiponectin, resistin, tumor necrosis factor α [TNF- α], interleukin-6 [IL-6]).
<i>Insulin resistance</i>	Decreased ability of insulin to act on its target tissues, resulting in compensatory hyperinsulinemia. Considered to be the earlier abnormality in the natural history of type II diabetes.
<i>Metabolic syndrome</i>	Syndrome characterized by the combination of central obesity, insulin resistance, dyslipidemia, and hypertension and correlated with high mortality rates due to cardiovascular complications, which aptly justify the description of the syndrome as the deadly quartet.
<i>Visceral obesity</i>	Obesity characterized by fat accumulation predominantly in the abdominal area, also called central or abdominal obesity.

The Stress Response

Stress is defined as a state of disharmony or threatened homeostasis. The concepts of stress and homeostasis can be traced back to ancient Greek history; however, the integration of these notions with related physiological and pathophysiological mechanisms and their association with specific illnesses are much more recent.

When faced with excessive stress, whether biological, physical, or psychological, a subject's

adaptive responses attain a stereotypic nonspecific nature, referred to by Selye as the general adaptation syndrome. During stress, attention is enhanced and the brain focuses on the perceived threat. Cardiac output and respiration are accelerated, catabolism is increased, and blood flow is redirected to provide the highest perfusion and fuel to the aroused brain, heart, and muscles.

The central control stations of the stress system are located in the hypothalamus and the brain stem and include the parvocellular corticotropin-releasing hormone (CRH) and arginine-vasopressin (AVP) neurons of the paraventricular nuclei of the hypothalamus and the locus ceruleus-norepinephrine system (central sympathetic system) (Figure 1). The hypothalamic-pituitary-adrenal (HPA) axis, together with the efferent sympathetic/adrenomedullary system, represent the effector limbs, via which the brain influences all body organs during exposure to threatening stimuli.

The Hypothalamic-Pituitary-Adrenal (HPA) Axis

The hypothalamus controls the secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary, which, in turn, stimulates the secretion by the adrenal cortex of glucocorticoids, mainly cortisol in humans. The principal hypothalamic stimulus to the pituitary-adrenal axis is CRH. AVP is a potent synergistic factor with CRH in stimulating ACTH secretion.

In nonstressful situations, both CRH and AVP are secreted into the hypophyseal portal system in a circadian, pulsatile fashion, with a frequency of about two to three secretory episodes per hour. Under resting conditions, the amplitude of the CRH and AVP pulses increases in the early morning hours, resulting in ACTH and cortisol secretory bursts in the general circulation. These diurnal variations are perturbed by changes in lighting, feeding schedules, and activity and are disrupted by stress.

Circulating ACTH is the key regulator of glucocorticoid secretion by the adrenal cortex. Glucocorticoids are the final effectors of the HPA axis and participate in the control of whole body homeostasis and the organism's response to stress. They play a key regulatory role in the basal activity of the HPA axis

Figure 1 Schematic representation of the stress system, highlighting the major central and peripheral components involved in the stress response. PVN, paraventricular nucleus; CRH, corticotropin-releasing hormone; LC, locus ceruleus/norepinephrine-sympathetic system; ACTH, adrenocorticotropic hormone. Activation is represented by solid lines and inhibition by dashed lines.

and in the termination of the stress response by acting at the hypothalamus and the pituitary gland and at higher brain centers. Glucocorticoids exert these actions via their glucocorticoid receptors and the rigorous regulation of a plethora of genes that are directly or indirectly implicated in several metabolic pathways, either activating them through positive glucocorticoid responsive elements (GREs) (e.g., genes encoding enzymes of glucose, lipid and amino acid metabolism, lipoprotein receptors, leptin) or repressing them through negative GREs (e.g., CRH, proopiomelanocortin, various cytokines).

The Sympathetic Nervous System

The autonomic nervous system provides a rapidly responding mechanism to control a wide range of functions. Cardiovascular, respiratory, gastrointestinal, renal, endocrine, and other systems are regulated by the sympathetic nervous system, the parasympathetic system, or both. Sympathetic innervation of peripheral organs is derived from the efferent

preganglionic fibers, whose cell bodies lie in the intermediolateral column of the spinal cord. These nerves synapse in the bilateral chains of sympathetic ganglia, with postganglionic sympathetic neurons that richly innervate the smooth muscle of the vasculature, the heart, skeletal muscles, kidney, gut, fat, and many other organs. The sympathetic system also has a humoral contribution, providing most of the circulating epinephrine and some of the norepinephrine from the adrenal medulla (Figure 1).

Consequences of Chronic Stress

Generally, the stress response with the resultant activation of the HPA and the sympathetic nervous system axes is meant to be acute or at least of a limited duration. The time-limited nature of this process renders its accompanying antireproductive, antigrowth, catabolic, and immunosuppressive effects temporarily beneficial rather than damaging. In contrast, chronicity of stress system activation would lead to the syndromal state that Selye described in 1936.

The prototypic example of chronic hyperactivation of the stress system is manifested in melancholic depression. Owing to a chronically hyperactive stress system, patients with melancholic depression may sustain several severe somatic sequelae, such as osteoporosis, features of the metabolic syndrome (e.g., visceral fat accumulation, dyslipidemia, increased blood pressure, impaired glucose tolerance), varying degrees of atherosclerosis, immunosuppression, and certain infectious and neoplastic diseases. When not treated, these patients have a compromised life expectancy curtailed by 15–20 years after excluding suicides.

In addition to melancholic depression, a spectrum of other conditions may be associated with increased and prolonged activation of the HPA axis, including childhood sexual abuse, anorexia nervosa with or without malnutrition, obsessive-compulsive disorder, panic anxiety, chronic active alcoholism, and alcohol and narcotic withdrawal.

More specifically, in the context of a mobilized adaptive stress response, glucocorticoids exert a broad spectrum of primarily catabolic effects as part of a generalized effort to utilize every available energy resource against the challenge enforced by the stressors. Thus, glucocorticoids increase hepatic gluconeogenesis and elevate plasma glucose concentrations, induce lipolysis (although they favor abdominal and dorsocervical fat accumulation), and cause protein degradation at multiple tissues (e.g., muscle, bone, skin) to provide amino acids that would be used as an additional substrate for oxidative pathways. In addition to their direct catabolic actions, glucocorticoids also antagonize the beneficial anabolic actions of growth and thyroid hormones, insulin, and sex steroids on their target tissues ([Figure 2](#)). This stress-related shift of the metabolism toward a catabolic state normally reverses upon retraction of the posed stressor. Chronic exposure to stress and HPA axis activation, however, is expected to progressively

Figure 2 Schematic representation of the detrimental effects of chronic stress on adipose tissue that may lead to clinical manifestations of the metabolic syndrome. Chronic HPA axis activation favors visceral obesity, with cortisol suppressing the beneficial effects of both the gonadal and growth hormone axis and directly stimulating adipocyte proliferation. Hypersecretion of TNF- α and IL-6 is proportional to the cytokines further stimulate the HPA axis activation, thus forming a deleterious vicious cycle. CRH, corticotropin-releasing hormone; ACTH, adrenocorticotrophic hormone; TNF- α , tumor necrosis factor α ; IL-6, interleukin-6; CRP, C-reactive protein. Stimulatory effects are represented by solid arrows and inhibitory effects by dashed arrows.

increase visceral adiposity, decrease lean body (muscle and bone) mass, and cause insulin resistance (Figure 2). Interestingly, the phenotype of Cushing's syndrome, characterized by abdominal and trunk fat accumulation and decreased lean body mass, in combination with various other manifestations of the metabolic syndrome (insulin resistance, dyslipidemia, hypertension, hypercoagulability, and hypercytokinemia), is present in a variety of pathophysiological conditions, categorized as pseudo-Cushing's states. This cushingoid phenotype, under certain conditions of chronic stress, could be attributed to stress-induced mild hypercortisolism, possibly combined with increased peripheral tissue sensitivity to glucocorticoids, the latter depending on the tissue-specific concentration and activity of glucocorticoid receptors, cortisol-binding protein (CBG), and 11 β -hydroxysteroid dehydrogenase type 1 (11 β -HSD1). Interestingly, 11 β -HSD1 is an isoform expressed primarily in the liver, adipose tissue, kidneys, and brain that catalyzes the conversion of the inactive cortisone to active cortisol in humans and, thus, locally augments the concentration of the bioactive hormone. This tissue-specific amplification of the cortisol action, mediated by 11 β -HSD1, appears to be very important for determining the tissue sensitivity to glucocorticoids and hence to the HPA axis hyperactivation, especially under conditions that potentiate 11 β -HSD1 activity, such as visceral obesity.

Depression and Diabetes

Until very recently, the attention of the scientific community had been focused on the emotional consequences of diabetes mellitus, rather than on the emotional causes of the disease. Depression rates are roughly twice as high among persons with diabetes as among persons without diabetes and are higher than those for most other chronic physical illnesses. A meta-analysis of 42 eligible studies showed that the presence of diabetes doubles the odds of comorbid depression, a stable finding in both controlled and uncontrolled studies not affected by sex, subject source, assessment method, or type of diabetes. Yet most of these findings are based on cross-sectional data, so they actually tell us very little about causal relationships.

Recently, however, significant evidence from population-based prospective studies in the United States and Japan shows that being depressed at baseline doubles the risk of subsequently developing type II diabetes and that this association is not explained by other risk factors for type II diabetes, including obesity, activity level, smoking, alcohol consumption, and family history of type II diabetes. Thus, in some

circumstances, depression may precede the onset of type II diabetes and may play an important role in its development. As described previously, depressive disorders are accompanied by increased sympathetic and sympatho-adrenal system activity, which is known to be associated with increased blood glucose and impaired glucose tolerance. Depressive disorders have also been associated with increased activity of the HPA axis, which results in an increased release of glucocorticoids, decreased glucose uptake, and elevated glucose levels. Depression may impair the ability to handle a carbohydrate load and then increase the risk of developing type II diabetes through a greater release of the counterregulatory hormones. More importantly, depression is associated with visceral fat accumulation, which is considered the key abnormality underlying the development of insulin resistance and the increased risk for type II diabetes and atherosclerosis. Changes in diet (e.g., unhealthy eating, alcohol consumption) and physical activity associated with chronic depression may also contribute to the glucose abnormalities that may develop.

Interestingly, effective treatment of depression in diabetic patients appears to produce a better glycemic control that is not due to differential effects of treatment on weight. Moreover, in controlled trials of cognitive-behavioral therapy, related improvements in depression produced significant improvements in glycemic control.

Stressful Life Events and Diabetes

Several studies have demonstrated a relationship of stress to glycemic control in samples of patients with type II diabetes. Stress can be managed through the use of behavioral stress management programs or through the administration of anxiolytic medications, both of which have been reported to improve long-term glycemic control in patients with type II diabetes. It is of note that staff-intensive individual training is not always required for a successful behavioral intervention, as group programs in a real-world setting can also result in clinically significant benefits for patients with type II diabetes.

A large recent study (the Hoorn Study) showed that a high number of rather common major life events, consistent with chronic psychological stress, during the past 5 years was indeed related to a higher prevalence of previously unknown type II diabetes, as well as to increased levels of visceral fat accumulation. These associations were independent of family history of diabetes, physical activity, heavy alcohol use, or low level of education. Furthermore, behavioral stress management programs, whether individualized or in groups, usually help.

Inflammation and Diabetes

It has been known for several decades that inflammatory stress is associated with concurrent activation of the HPA axis. Indeed, cytokines and other humoral mediators of inflammation are potent activators of the central stress response, constituting the afferent limb of the feedback loop through which the immune/inflammatory system and the central nervous system communicate (Figure 3).

All three inflammatory cytokines tumor necrosis factor α (TNF- α), interleukin-1 β , and interleukin-6 (IL-6) can cause stimulation of the HPA axis alone, or in synergy with each other. There is evidence to suggest that IL-6, the main endocrine cytokine, plays the major role in the immune stimulation of the axis. Some of the activating effects of cytokines on the HPA axis may be exerted indirectly by stimulation of the central catecholaminergic pathways. Also, activation of peripheral nociceptive, somatosensory, and visceral afferent fibers would lead to stimulation of both the catecholaminergic and CRH neuronal systems via ascending spinal pathways.

In addition, TNF- α interferes directly with insulin signaling causing insulin resistance, and, together with the other inflammatory cytokines, has direct actions on the endothelium promoting the atherogenic process. Interestingly, TNF- α is overproduced by adipose tissue in obesity and appears to be one of the

molecular links between obesity insulin resistance/diabetes and atherosclerosis. Increased production of other adipokines, such as resistin, visfatin, and leptin, and decreased production of adiponectin with expanding obesity, further increase the inflammatory load and the risk for insulin resistance and atherosclerosis.

Indeed, an increasing body of evidence supports a possible role for inflammation in the pathogenesis of type II diabetes. Thus, in the Women's Health Study, an ongoing U.S. primary prevention randomized clinical trial initiated in 1992, elevated levels of C-reactive protein (CRP) and IL-6 predicted the development of type II diabetes. Other common markers of inflammation (fibrinogen, haptoglobin, white-cell count, sialic acid) are also associated prospectively with the development of diabetes in adults. Furthermore, chronic subclinical inflammation relates independently to insulin resistance, even in nondiabetic subjects. It is therefore likely that anti-inflammatory therapy may be beneficial in improving insulin resistance and preventing the development of type II diabetes. Interestingly, thiazolidinediones, a new class of insulin sensitizers, also have anti-inflammatory properties, reducing CRP and TNF- α levels. Moreover, the observed significant reductions in the hazard of becoming diabetic with statins may be attributed at least partly to the anti-inflammatory properties of these drugs.

Figure 3 Schematic representation of the interactions between the pro-inflammatory cytokines, the HPA axis, and the immune system response. TNF- α and IL-6 secretion by the adipocytes is continuous and proportional to body mass index (BMI). TNF- α and IL-6 secretion by the immune cells at inflammatory sites occurs in a cascade-like fashion, with TNF- α appearing first followed by IL-6. TNF- α , tumor necrosis factor α ; IL-6, interleukin-6; CRH, corticotropin-releasing hormone; ACTH, adrenocorticotrophic hormone. Stimulatory effects are represented by solid arrows and inhibitory effects by dashed arrows.

Conclusion

Chronic stress seems to contribute to the development of visceral obesity and, hence, of type II diabetes and atherosclerosis, and, conversely, the accumulation of visceral adipose tissue constitutes a chronic stressful state. The mechanisms that mediate this documented reciprocal relation and cause the derangement of the metabolic homeostasis are the subject of many recent research efforts, and their characterization will hopefully provide novel insights into the pathogenesis of type II diabetes and cardiometabolic complications and help the quest for more specific and effective therapeutic interventions. Moreover, treating depression in and providing effective stress management programs for people predisposed to diabetes may add a new dimension of primary prevention of type II diabetes to the treatment of traditional risk factors such as obesity, diet, and physical inactivity.

Summary and Conclusion

Glossary

<i>Adipogenesis</i>	The growth of adipose tissue, increasing fat mass.
<i>Angiogenesis</i>	The formation of new vessels from preexisting ones; called ischemic angiogenesis in areas of poor blood flow (ischemia).
<i>Atherosclerosis</i>	The inflammatory response of blood vessels; the buildup of atherosclerotic plaques causing a lesion that contains the abnormal growth of vascular smooth muscle cells (neointima), deposition of matrix proteins, aggregation of platelets (thrombus formation), and formation of lipids.
<i>Balloon angioplasty</i>	A procedure used by cardiologists that involves the insertion of a catheter whose balloon can be inflated to re-open an artery that was closed (occluded) by an atherosclerotic plaque.
<i>Macrophages</i>	Immune cells with phagocytotic capabilities.
<i>Neuropeptide Y (NPY)</i>	A 36-amino-acid peptide present primarily in the neurons of the brain and in the peripheral nervous system, rich in tyrosine (Y, in the one-letter code used for amino acids).
<i>Obesity</i>	Increased fat mass and weight above 30% of normal.
<i>Restenosis</i>	The repeated closure of a vessel previously opened by balloon angioplasty or by other vascular procedures such as the insertion of a stent.

Stress

Sympathetic nerves

Vascular remodeling

The real or perceived alteration of internal or external environment that elicits bodily responses (stress responses).

Part of the autonomic or vegetative nervous system that innervates most blood vessels and organs of the body; essential in body's responses to stress.

Any change to vessel structure such as the excessive or abnormal growth of vascular smooth muscle in the medial layer of the vessel or the sprouting of new vessels (angiogenesis).

Structure and Localization of NPY in the Body

Neuropeptide Y (NPY) is a 36-amino-acid brain peptide, one of the most abundant in the body. It is formed from a 97-amino-acid peptide, preproNPY, which contains a signal peptide targeting the precursor molecule to the endoplasmic reticulum. Specific convertases subsequently cleave the preproNPY to form a mature and amidated NPY(1–36), which is biologically active. An additional processing product is the C-terminal peptide of NPY (CPON), a peptide whose actions are relatively unknown. Inside neurons, mature NPY(1–36) is stored in large dense core vesicles and emptied into the synaptic cleft during nerve depolarization. Recent research shows that, in addition to its neuronal sources, NPY is expressed extraneuronally in the endothelial cells and platelets of some species, where it acts as an autocrine and paracrine regulator of cell functions.

In the central nervous system, NPY is richly expressed in the hypothalamus, hippocampus, brain stem, and cortex, and it is colocalized with classical neurotransmitters such as catecholamines and GABA. In the periphery, NPY is present in all the sympathetic nerves innervating the blood vessels and in the chromaffin cells of the adrenal medulla, where it is colocalized with norepinephrine (NE) and epinephrine, respectively. The most abundant vascular NPY-ergic innervation is found in small arteries in the kidneys and the mesenteric bed. The third, least source of NPY in the body is the gut parasympathetic and enteric nerves, in which NPY is present in small and large intestines. In the gastrointestinal tract, two other peptides belong to the same family as NPY: peptide YY (PYY) and pancreatic polypeptide (PP). They act as hormones rather than as neurotransmitters; hence, they are not a major focus of this review.

The whole NPY peptide family evolved from an ancient ancestor gene and has maintained a high degree of conservation of structure. NPY, in particular, is 90–99% homologous among a wide range of species; for example, rat and human NPYs are identical. The critical C-terminal portion of NPY, as well as PYY, which shares most of its affinity for its receptors, has been 100% conserved throughout evolution, suggesting that it plays an important physiological role.

The NPY Receptor System and Major Actions

Determining what NPY's physiological role is has been a challenge. Early Swedish studies suggested potent cardiovascular effects for NPY – arterioconstriction and increased blood pressure, which are resistant to the blockade of α -adrenergic receptors. In a landmark experiment in 1982 on the cat submandibular gland, Lundberg et al. showed that the effect of NPY is mimicked by prolonged sympathetic nerve stimulation in the presence of total adrenergic blockade and suggested that NPY is a mediator of nonadrenergic sympathetic transmission. Determining the significance of these actions in the cardiovascular system required the cloning of the NPY receptors and the development of selective receptor inhibitors.

The first receptor that was cloned for rat, mouse, and humans was the Y1 receptor. It is a Gi-coupled receptor that is predominant in the blood vessels, where it mediates vasoconstriction and the potentiation of vasoconstriction exerted by NE and other agents. The Y1 receptor is also widely expressed in neurons in the central and peripheral nervous systems, where it mediates a range of functions from anxiolysis and appetite stimulation to neuronal cell proliferation and analgesia. Recently, this receptor was found to be present in T- and antigen-presenting cells, where it regulates the proliferation and functions of these cells. The Y1 receptor requires the whole NPY(1–36) molecule for activation; therefore, peptidases that cleave N-terminal amino acids inactivate Y1 receptor-mediated activities (i.e., act as endogenous Y1 antagonists). The major enzyme in this group is dipeptidyl peptidase IV (DPPIV), which is present ubiquitously in endothelial, immune cells and macroglia, and forms NPY(3–36). The other known protease is aminopeptidase P (APP), expressed on vascular smooth muscle and other cells, which forms NPY(2–26).

On cleavage, C-terminal fragments of NPY can be detected in the circulation and remain active, but

change their receptor affinities and become poor activators for or are inactive at Y1 while having a high affinity for the other, non-Y1 receptors. Up to five more receptors have been cloned so far: Y2, Y4, Y5, and Y6. All of them are Gi-coupled. The remaining Y3 receptor has been characterized pharmacologically as the one that is NPY-preferring, that is, not activated by PYY; it has not been cloned. Although a number of tissues appears to display such a pharmacological profile, for example, the brain stem, this receptor is now considered nonentity.

Y2 receptors are the predominant neuronal presynaptic receptors in the brain and the periphery, where they inhibit neurotransmitter release. They act as NPY's own autoreceptors as well as inhibiting the release of NE and other neurotransmitters such as ATP. Interestingly, the Y2-mediated inhibition appears to increase at a higher frequency of neuronal activity. In the central nervous system, the inhibitory effects of Y2 receptors on NPY release often result in the inhibition of either Y1- or Y5-receptor-mediated responses. For that reason, Y2 receptor antagonists are now emerging as the preferred drugs for several mental disorders (e.g., anxiety and depression) because they allow targeted therapy to the sites of overstimulation and limit other widespread effects in the brain that Y1- or Y5-receptor antagonists could otherwise have.

Postsynaptic Y2 receptors have also been found in the blood vessels, where they regulate the vascular tone; these changes range from vasoconstriction to vasodilation and angiogenesis, depending on the release from the endothelium of secondary mediators, such as nitric oxide. Whereas Y1 and Y2 receptors are constitutively expressed in unstimulated tissues, Y5 receptors appear not to be expressed alone and are often induced on demand in response to cellular stress. Initially, the Y5 receptor has been cloned from the hypothalamus as a feeding receptor, mediating NPY's action to stimulate appetite. It shares with the Y1 receptor the same promoter sequence, although read in the opposite direction, and appears to be regulated in concert with the Y1. Recently, we reported that Y5 is inducible in endothelial and vascular smooth muscle cells by tissue ischemia and injury.

Sources of NPY Release in the Circulation

The role of NPY as a mediator of nonadrenergic sympathetic transmission has been well documented by several groups in early studies both *in vitro* and *in vivo*. It became generally accepted that the peptide is released by more intense or prolonged nerve stimulation than that required for the release of NE. The

differential release of NPY and NE has also been seen using various stressors as stimulators of sympathetic nerve activity. A plausible explanation has been the different distribution of these neurotransmitters in the secretory granules, with NPY being stored in the large and NE in the small dense core vesicles. Although NE is also stored in the large vesicles, those constitute only a minor portion of the overall adrenergic pool and hence are minor determinants of the amount of released NE. However, recent studies with cultured cells have demonstrated that NPY is secreted from neuronal and non-neuronal cells at an even lower intensity of stimulation than seen before. In addition, NPY has been found to exert biological effects at extremely low concentrations (submolar to picomolar range). The *in vivo* detection of such minimal amounts of the peptide is clearly beyond the limits of currently used methods and, hence, cannot be documented at the present time.

Radioimmunoassays and enzyme-linked immunoassays have been the most commonly used methods for detecting circulating and tissue-derived NPY. Plasma NPY-immunoreactivity (NPY-ir) was found to vary among the species, with human and porcine levels being the lowest (picomolar range). Rats and some mice have higher NPY levels (submolar to nanomolar range) due to the expression of NPY extraneuronally in megakaryocytes and platelets. In these animals, NPY-containing platelets become a transport system delivering the peptide to the sites of platelet activation. Although healthy humans do not have NPY in platelets, some diseases such as atherosclerosis appear to induce its expression. The significance of these findings remains to be determined; however, animal studies suggest that platelets, as well as NPY, play a critical role in vascular restenosis after balloon angioplasty. Interestingly, the levels of NPY-ir in the systemic arterial and the coronary sinus plasma increase during angina due to either myocardial ischemia or panic attack, indicating that intracardiac rise in NPY may contribute to vascular occlusion and be involved in thrombus formation, vasospasm, and vascular remodeling.

The third source of circulating NPY is the endothelium; however, a controversy still exists about whether these cells actually secrete the peptide into the bloodstream. NPY is an autocrine growth factor and stimulates endothelial cell migration, proliferation, and differentiation into capillaries by an action mediated primarily by Y2 and Y5 receptors, with an active role played by DPPIV (components of NPY's angiogenic system are expressed in these cells). Ischemia and cellular stress both upregulate NPY, Y2 and Y5 receptors, and DPPIV.

Stress-Induced Release of NPY from Peripheral Sympathetic Nerves

The highest plasma NPY-ir levels in humans were noted in newborns after vaginal delivery. This is probably due to the stress of delivery; babies born by cesarean section have significantly lower peptide levels. With aging, circulating NPY levels in humans and in animals decrease, but stress continues to stimulate its release. Various stressors have been studied and found to exert differential effects on plasma NPY, by itself and in relation to catecholamines. Of those, the strongest stimulus for NPY release appears to be exposure to cold temperature and strenuous exercise, particularly when combined with hypoxia. Interestingly, there is a gender difference in the response to cold and/or treadmill exercise in both humans and rodents. Although there is no sexual dimorphism in the basal circulating NPY levels, males increase their plasma NPY-ir levels more than females following both stressors. In rats and in humans, this does not appear to be due to estrogens because ovariectomy and estrogen replacement has no effect on cold- and exercise-induced NPY responses. Subsequent studies in gonadectomized rats confirmed that the gender difference in the NPY system is due to testosterone, which strongly upregulates NPY gene expression. Sex differences in stress-induced plasma NPY responses were paralleled by greater hypertensive effects of stress in males, implying that the peptide may play a role in essential hypertension, which is more frequent in men than in premenopausal women.

Interestingly, other commonly used laboratory stressors such as immobilization stress in rats or mental arithmetic in humans failed to yield measurable changes in circulating NPY-ir levels using current analytical methods. Interestingly, a rise in plasma NPY levels in humans during bicycle exercise is augmented by the blockade of α -2-adrenergic receptors, indicating that NPY release is under physiological (presynaptic) inhibition by these receptors. The depletion of catecholamines from the sympathetic storage vesicles by reserpine was also shown to increase the NPY-dependent component of the neurogenic response to nerve stimulation (after a transient fall in blood pressure due to the removal of adrenergic vascular tone). Ganglionic blockade with chlorisondamine eliminated the NPY release and resulted in a complete loss of sympathetic tone. This experimental protocol elegantly demonstrated that although NPY may not be the primary neurotransmitter maintaining normal vascular tone and blood pressure, it is the alternative pathway to adrenergic transmission and is one that can either compensate for the loss of it or

amplify or dominate over the adrenergic response. An example of the former may be sympathetic dysautonomia, in which patients have impaired adrenergic transmission but are able to compensate for it; an example of the latter may be situations in which NPY signaling is selectively enhanced by cold exposure and a high-fat and high-sugar diet.

Chronic Stress, NPY, and Vascular Remodeling after Balloon Angioplasty

Although the examples so far illustrate the ability of the body to secrete NPY in response to acute stimulation of the sympathetic nerves, the role of this peptide neurotransmitter as a stress mediator can be understood best in chronic stress. In several diseases in which sympathetic activity is increased, circulating NPY-ir levels are markedly elevated. Some of the highest levels in humans were found in congestive heart and renal failure, in which they strongly correlated with and might be predictors of end-organ damage.

The actions of NPY also differ when it is applied chronically. In the cardiovascular system, acutely, NPY causes a slow onset, long-lasting vasoconstriction and increase in blood pressure at nanomolar concentrations consistent with the levels yielded by acute intense stress, for example, the immersion of a hand in ice water for humans or standing in ice-cold water for rodents. *In vitro*, such NPY concentrations applied for 1–14 days to cultured vascular smooth muscle and endothelial cells stimulates their migration, proliferation, differentiation, and release of secondary growth factors, leading to sustained cell growth. In these *in vitro* conditions, NPY also acts at lower than vasoconstrictive concentrations (submolar to picomolar range) and acts as an autocrine and paracrine growth factor. In *ex vivo* cultured aortic rings, NPY is potently angiogenic and leads to the formation of long vascular sprouts, resembling normal vessels. For some cells, such as neuroblastomas (tumor cells derived from sympathetic neurons), NPY is essential as a cell growth factor, whereas for others, such as Ewing's sarcoma, NPY is apoptotic. Thus, growth-modulatory actions are mediated by its multiple receptors and the final effect depends on the type of receptors and cell-specific signaling pathways. Whereas the growth-promoting effects of the peptide on vascular smooth muscle are mediated by Y1 receptors, NPY's angiogenic activities are mediated primarily by Y2 receptors and require the conversion of NPY(1–36) to NPY(3–36). What is the significance of these actions *in vivo*? Would the chronic stress-induced release of NPY mimic the peptide's effects seen *in vitro* and, if so, which ones?

We approached these questions using cold-water stress (animals standing in 0.5–1 cm of ice-cold water at the bottom of their cages) combined with experimental conditions known to trigger vascular remodeling. In rats, balloon angioplasty-induced arterial injury or intermittent chronic cold by itself within 2 weeks increased the platelet NPY-ir levels, but only cold stress elevated the plasma NPY. This suggested that, although plasma NPY responses are probably due to sympathetic nerve activation, platelet NPY may reflect changes originating in the bone marrow, in the megakaryocyte synthesis of NPY. This notion has been supported by studies using mice expressing or not expressing NPY in megakaryocytes. Both rats and mice, which have additional source of NPY in the bone marrow, developed neointima in the angioplasty-injured vessels, whereas mice deficient in megakaryocyte/platelet NPY were resistant to vascular injury and did not develop neointima. Whether platelet NPY is critical for neointima formation in rodents, and in humans, is currently being investigated.

NPY that is exogenous or released from sympathetic nerves by cold stress, on the other hand, augments neointima in all rodent strains, with or without platelet NPY, although the extent of the amplification is significantly greater in the former. In angioplasty-injured rat carotid arteries, NPY and stress alike induced the occlusion of the angioplasty-injured vessel with a lesion, which contained neovascularized neointima, thrombus, matrix, lipids, and increased invasion of macrophages – the elements of advanced atherosclerotic lesion. This occurred in an animal devoid of any lipid abnormalities within only 2 weeks and was completely prevented by a selective Y1 receptor antagonist. How it is possible for an antagonist of only one receptor to block such a complex process as restenosis and atheroma-like lesion formation is indeed puzzling. The critical role of Y1 receptors, however, is better understood when we consider the environment into which NPY is released following sympathetic nerve activation and vascular injury.

Critical Role of Y1 Receptors in Immune System and Angioplasty-Induced Restenosis

Chronic stress exerts direct effects not only in the cardiovascular system but also on the immune cells, commonly manifested as a greater incidence of infection during periods of stress. Although many mediators, including catecholamines and glucocorticoids, contribute to this effect, the role of NPY has not been considered until recently. Wheway et al. recently

reported that NPY and its Y1 receptors are essential for the normal functioning of T cells. The direct stimulation of Y1 receptors on T cells leads to the suppression of their Th1-type response and decreased secretion of interferon- γ and tumor necrosis factor- α . For that reason, Y1 receptor agonists are protective against Th1-mediated inflammatory conditions such as experimental autoimmune encephalitis, a model of multiple sclerosis. However, NPY can also exert stimulatory actions on immune cells via the same type of Y1 receptors on antigen-presenting cells. The loss of that response early during development in germline Y1 receptor knockout mice led to the impaired functioning of antigen-presenting cells, reduced number of functional T cells, and, hence, lowered Th1-mediated responses. Paradoxically, Y1 receptor deficiency protects against colitis, which depends on Y1-mediated activation of antigen-presenting cells.

The central role that the Y1 receptor plays in the immune system is due to a widespread distribution of that receptor, not only in vascular smooth muscle cells but also in all immune cells, including T cells, macrophages, neutrophils, and eosinophils. NPY activates monocytes and stimulates their phagocytosis, migration, and proliferation. This is likely to have implications outside infectious or autoimmune diseases because inflammatory responses are now considered important pathogenic mechanisms in many other conditions, including atherosclerosis, ischemic angiogenesis, and obesity. Thus, we can imagine that the stress-induced activation of the sympathetic nerves during vascular injury may not only exert direct effects on vascular smooth muscle and platelets but may also activate immune cells residing in the vascular wall and stimulate their transmigration from the bloodstream. Because all these cells express Y1 receptors, it is likely that nerve-released NPY starts a cascade of events by activating this receptor on cells adjacent to the nerve terminals. In addition, the Y1 receptors are upregulated by angioplasty, and this increase is further amplified by stress; as a result, Y1 receptors become widely expressed in neointima, macrophages, and other immune cells.

Because the Y1 receptor antagonist prevented the entire process of restenosis in rodent models of balloon angioplasty, we can also predict that Y1 deficiency is protective against stress-induced restenosis and, that Y1 receptor antagonists may be a new class of drugs for this condition. Our studies also suggest that stress is a risk factor for restenosis, facilitating the formation of atheroma and vascular hyperplasia even in the absence of hyperlipidemia. Such striking changes as those induced by stress have never been previously induced in animals without genetic manipulations of lipid metabolism. Although more

studies are needed to establish the clinical relevance of these findings, two lines of evidence strongly suggest that high NPY levels, and NPY release by stress, play a role in human atherosclerosis. First, an NPY signal peptide polymorphism, Leu7Pro, a common gain-of-function mutation occurring in northern European populations was found to lead to higher plasma NPY levels in response to stress, along with hyperlipidemia and accelerated atherosclerosis. Second, the induction of NPY in platelets was recently discovered in patients with atherosclerosis, similar to what previously was reported to occur in patients with severe depression. Current studies in our lab are being conducted to confirm whether stress in humans accelerates atherosclerosis by releasing NPY from the sympathetic nerves and/or platelets.

Chronic Stress and Angiogenesis: Implications for Ischemic Revascularization and Adipogenesis

If stress releases NPY from nerves and/or platelets, what determines whether the peptide exerts vasoconstrictive vasoproliferative effects leading to vascular hyperplasia via its Y1 receptors or is angiogenic leading to the increased vascularization of the tissue via its Y2 receptors (Figure 1)? We addressed this question first using a model of ischemic limb, in which

Figure 1 Effects of stress on central and peripheral NPY systems. a, Central nervous system effects; b, peripheral effects in sympathetic nerves. DPPIV, dipeptidyl peptidase IV; HPA, hypothalamic-pituitary-adrenal; Y1R, NPY receptor 1; Y2R, NPY receptor 2.

spontaneous revascularization is incomplete and produces a deficit in blood flow. Limb ischemia induced by unilateral femoral artery occlusion, like angioplasty described previously, elicited a local release of NPY from the sympathetic nerves. However, in contrast to the effects of angioplasty on the vascular wall, tissue ischemia also stimulated NPY synthesis in the endothelium and shifted the expression of its receptors in the ischemic limb toward Y2 and DPPIV, the elements of NPY's angiogenic system. The local administration of NPY at the site of ischemic skeletal muscles amplified these responses and, in addition, also induced Y5 receptors while augmenting angiogenesis and arteriogenesis in the limb. Exposure to cold, intermittently for 2 weeks, however, did not mimic NPY's actions and actually inhibited ischemia-mediated changes in NPY receptor expression. Although these studies are still in progress, the data suggest that NPY's angiogenic receptor system, NPY-Y2/Y5-DPPIV, is not sufficiently activated during stress. Yet unidentified factors appear to inhibit the NPY's angiogenic switch and prevent the peptide from fully expressing its angiogenic capabilities in the ischemic tissues. Given the fact that Y2 and Y5 receptors and DPPIV are expressed in the ischemic skeletal muscles, the administration of Y2/Y5 receptor agonists may become useful as a revascularization therapy. Alternatively, the activation of DPPIV, the converting enzyme, could serve as a way to shift stress-induced NPY release away from vasoconstriction and vascular hyperplasia via its Y1 receptors and toward Y2/Y5-mediated angiogenesis.

Such a switch appears to occur spontaneously in the white adipose tissue under the conditions of a high-fat and high-sugar diet; under this condition, stress causes a marked upregulation of NPY, Y2, and DPPIV. This leads to the activation of angiogenesis, which then promotes further tissue growth and, thus, may contribute to the development of adiposity and obesity. Previously, others have proposed using anti-angiogenic therapy for the treatment of obesity, but the physiological mechanisms specific to fat have not been uncovered. This new area of research should shed light on the pathogenesis of obesity, which has become an epidemic concurrently with the rise in the levels of daily stress. The relation between the two processes, stress and obesity, although anecdotally acknowledged, has never been established scientifically.

Summary and Conclusion

In addition to the roles of NPY in the cardiovascular system described here, the peptide exerts pleiotropic actions on essentially every tissue and the regulatory

system of the body. In the brain, NPY is potently anxiolytic, sedative, and anticonvulsive and inhibits locomotor activity – actions consistent with the anti-stress effects rather than the pro-stress actions that it exerts in the periphery (Figure 1). Those central actions have implicated the peptide in anxiety and mood disorders, in which NPY levels in the cerebrospinal fluid are decreased. The peptide is also one of the most powerful stimulants of food intake, particularly of carbohydrates, resembling stress-induced cravings for sweets, and thus plays a role in appetite disorders, both obesity and anorexia. At the same time, NPY modulates a number of hormonal systems, from the hypothalamic-pituitary-adrenocortical and hypothalamic-pituitary-gonadotropin axes to the secretion of growth hormone and insulin, slowing down puberty and suppressing reproductive functions (Figure 1). In addition to its peripheral actions, centrally, NPY also inhibits lipid metabolism and energy expenditure, lowers body temperature, and promotes fat storage (Figure 1).

The two sites of NPY's actions, the brain and the periphery, have been studied so far in separation and little is known about their reciprocal relationship. It appears, however, that, as with many other neuro-hormonal systems, central and peripheral NPY are also regulated by negative feedback loops, with central NPY being often inhibitory for peripheral NPY. A primary example of such a reciprocal inhibitory relationship is the inhibitory effect of hypothalamic NPY on peripheral sympathetic activity, lowering plasma NPY levels. In conditions such as posttraumatic stress disorder, resulting from severe trauma, the balance between the central and peripheral NPY responses appears to be disregulated at both brain and the peripheral levels. The regulation of the cardiovascular system by NPY in this and other stressful situations is clearly only a part of the patterned body responses to stress and the patterns that vary with different stressors.

The integrated response of the NPY system in many ways resembles the body's adaptation to hibernation. Several lines of evidence support that hypothesis. First, cold temperature is one of the most potent stimuli for NPY release. Second, in preparation for hibernation, an animal requires cardiovascular adaptation, increased blood pressure and heart rate, to allow it to search for food; such a response is provided by peripherally released NPY. Third, in the presence of carbohydrate-rich food, the NPY stress response also promotes lipid storage, which an animal preparing for hibernation needs. Once this is accomplished, sympathetic activity is expected to fall and the animal's bodily functions to slow down. NPY's central activities support such actions as well,

with its effects of decreased body temperature, energy expenditure, and reproductive functions.

The final intriguing support of the hibernation hypothesis is suggested by genetic epidemiology. A Leu7-to-Pro7 polymorphism in the NPY signal peptide has been found to be common in northern European populations. Interestingly, there is a strong north-to-south gradient of this mutation, which is absent in Africa, Asia, and South America (unless in descendants of northern Europeans). The Leu7Pro polymorphism associates with increased NPY responses to stress, hyperlipidemia, and obesity – which at some time could have afforded an evolutionary protection, improving survival in cold temperatures. Unfortunately, there are also unwanted effects of this mutation. It is linked to accelerated atherosclerosis, diabetic retinopathy and nephropathy, and alcoholism – perhaps the price that humans paid for not adjusting to the rules of nature, eating and drinking too much while exercising too little all year long.

The importance of NPY in physiology was questioned by the studies of the Palmiter group who showed that life without NPY, in NPY-knockout mice, is apparently normal. The mice eat, develop, and breed normally and do not have any specific phenotype. They do, however, exhibit a lower threshold for seizures and have higher preference for alcohol – possibly offering a new model for epilepsy and alcoholism. Yet the true contribution of NPY to animal physiology can only be appreciated when the adaptation to chronic stress is considered. When laboratory animals are housed in a constant environment, without any stress, their life may seem normal. However, if NPY-knockout mice are subjected to stress, particularly chronically and in combination with poor diet, their ability to develop proper cardiovascular, immune, and metabolic adaptations might be impaired. In years to come, more studies will be required to understand the full implications of NPY's release and activities in all of the body's sources: the brain, peripheral sympathetic nerves, and the enteric system, as well as its extraneuronal expression in platelets, endothelium, and immune cells.

Jihad

manner and may even include compartmentalizing the event from one's ambitions and daily life. One bomber for example, when planning his attack, suggested that he could not carry a bomb until after his university exams – suggesting that while on the one hand he acknowledged that he was going to his death he was able separate this reality so completely from his mind that he still felt the need to complete his exams prior to going to explode himself.

Is an Islamic word and makes reference to the teachings of the Prophet Muhammed as they are recorded in the Koran and Sunnah, in which believers are taught to struggle on two levels: the first and most important being referred to as the greater jihad in which an individual strives inwardly in an effort to resist evil and live a pure life according to the tenets of Islam. The lesser jihad involves a political or military struggle to further and/or defend Islam and Islamic lands and people. In the current global context certain ideologies promoting terrorism are referred to by some as promoting militant jihad. For example the US Department of Justice has referred to jihad as the use of violence, including paramilitary action against persons and governments deemed to be enemies of a fundamentalist version of Islam.

Glossary

Dissociation According to the American Psychiatric Association, the essential feature of a dissociative disorder is “a disruption in the usually integrated functions of consciousness, memory, identity or perception of the environment” – American Psychiatric Association (1994) *Diagnostic and statistical manual of mental disorders (4th ed.)*. Washington, D.C. In the case of suicide terrorism, this means an emotional barrier is unconsciously erected walling off the negative emotions generated by choosing to die in this

Posttraumatic stress disorder (PTSD)

Is a person's individualistic response to a traumatic event (see psychological trauma below) in which the following responses occur: an inability to integrate and respond well to a traumatic event on a cognitive, emotional and/or on a sensory level resulting in 1) reexperiencing behaviors including flashbacks, nightmares and unbidden and upsetting thoughts of the event; 2) avoidance of reminders of the event including feelings of social alienation; 3) bodily arousal in response to reminders of the event including shakiness, sweaty palms, loss of concentration, irritability, trouble falling and/or staying asleep; 4) loss of function in life domains including work, intimate and family relationships etc. and 5) all of these symptoms lasting for more than thirty days following the event. Shorter, (less than thirty days following the trauma) but equally disabling and intense, dissociative responses to psychological traumas which at times might transition into PTSD, are labeled as acute stress disorders.

Suicide or human bomber

A suicide bomber as anyone who goes so far as to strap on a bomb, drive a vehicle filled with explosives to a target, or who otherwise attempts to detonate an explosive device on an airplane, in a subway, train, car, or elsewhere with the aim of dying to kill – irrespective of whether or not the bomber actually died in the attack or was successful in detonating – as that is often not within the bomber's control. We take the fact of being to the point of willingly strapping on a bomb or other type of improvised explosive device or driving a vehicle loaded with explosives to a target as sufficient evidence of seriousness of the intent to suicide and see the end result, which is often out of the hands of the bomber as less meaningful than the intent implied by these actions. An actor who arrives at a scene with a weapon, most often a gun, in order to shoot as many victims as possible prior to being killed himself may also be seen as a suicide terrorist, but is obviously not a human bomber. Psychologically the preparation and action of going on such a killing spree in which one's death is nearly guaranteed is very similar to that of a human bomber.

Terrorism

Has many definitions but is generally viewed as political violence carried out by politically organized non-state actors/groups with the intent to destroy property, injure, take hostage and/or kill

civilians and thereby intimidate and influence a wider witnessing audience and to effect political, religious or ideological change in both the targeted population and its government's responses; as well as to drum up support among the group's own sympathizers. Terrorism relies heavily upon the mass media to amplify the psychological effect of attacks made on relatively small numbers of victims by relaying horrifying images to a much larger witnessing audience. There is considerable controversy over who is defined as terrorists, particularly in situations where non-state actors (i.e. freedom fighters, rebels or guerilla fighters) could be also seen as leading legitimate rebellions in occupied territories but who nevertheless use similar tactics as terrorists such as using civilians as shields and indiscriminately targeting civilian as well as military targets.

Psychological trauma

Involves an experience in which an individual experiences a serious threat (real or perceived) to his own life or bodily integrity or witnesses death or threat of life or dismemberment in another and responds with overwhelming feelings of fear, horror and helplessness. In this experience the person is typically psychologically overwhelmed and unable to integrate his emotional, cognitive and sensory experiences in a normal manner and a peritraumatic dissociation may result immediately or in some time following the event. Acute or posttraumatic stress disorder may result.

Suicide terrorism is fast becoming one of the most pestilent global afflictions of the twenty-first century. As a terror tactic, it is one of the most lethal. Strategically it functions as a relatively cheap and effective means of upsetting the political, economic, and military situation of a region and has become one of the major threats to peacekeeping and peace-making efforts. Yet, as prevalence rates and death tolls from suicidal attacks increase, policy makers are still working in the dark trying to find the most effective policy responses to the emergence of this new and poorly understood security threat. Currently there is an extremely small empirical research database on which policy makers may base their understanding of the genesis of suicidal terrorism in order to work toward its prevention and eradication. Comprehending this growing threat and learning to combat it effectively on both the local and international levels is extremely relevant to current public policies aimed at promoting

peace and stability. This article briefly discusses the background of modern-day suicide terrorism, its migration around the world, and the tendency of modern-day terror groups to embrace it as a tactic. Drawing from field research in four distinct world regions, I give an in-depth analysis of the social and psychological factors in the genesis of human bombing.

Focusing on social and psychological factors within the sponsoring groups, the individual bombers, and the societies in which they exist, I have identified two main differing motivational sets on the level of the individual actors for the genesis of suicide terrorism. The first of these is trauma-based, occurs within zones of active conflict, and is often nationalistic, is viewed in terms of self and community defense, is expressive regarding attempts to mete out justice to the perceived enemy occupier, and includes acts of revenge by actors who are often so traumatized that they have become deeply dissociative and even refer to themselves as “already dead.” The second motivational set applies to actors outside the active zones of conflict, who are nevertheless influenced by them (through the Internet, video footage, pictures, and propaganda) and who frequently develop a deep sense of secondary traumatization. The actors in the second motivational set are generally vulnerable to terrorist ideologies due to a sense of alienation, marginalization, lack of life meaning, and lack of positive identity and are usually recruited through exposure via the Internet or via close-knit family and friendship networks. In both motivational sets, it is important to recognize that individuals are generally not motivated to take part in suicide terrorism without a guiding ideology and that they are also generally in need of an organization to equip and guide them to carry out their acts (although a rare few have acted on their own; Argo, 2004; Speckhard, April 2005). They generally are more willing to take part in suicide terrorism when there is broad-based support for suicide terrorism in the sector of the community in which they find their sense of belonging.

The History of Suicide Bombing

Dying to kill is not new.¹ What is new is that, in modern times since the mid 1980s, the tactic of

suicide terrorism has been repackaged and reborn. It has suddenly taken off like a wildfire spreading from Lebanon to Palestine, Sri Lanka, Chechnya, Morocco, Indonesia, Turkey, Afghanistan, and Iraq (where there is, on average, one suicide bomber per day); and now, sadly, it has spread even to those originating in Europe (i.e., the infamous shoe bomber, Richard Reid; the Mike's Place bombers in Israel; and Europeans going as bombers to Iraq and Afghanistan) and European-bred bombers now even targeting Europe itself. What combination of factors and conditions have made this tactic suddenly so popular that citizens of countries that have no history of suicide terrorism are suddenly willing to recruit themselves as human bombs, making this a main tactic of choice for many terror groups worldwide?

The Success of Suicide Terrorism

Looking back in recent history, we see that the current spate of modern-day suicide terrorism began in Lebanon in the 1980s when terrorists used suicide truck bombs to attack first the U.S. Embassy and later the barracks of the U.S. Marines and French troops, actions that led to the troops deciding to remove themselves from Beirut and position themselves offshore – this was viewed as a huge strategic victory by the terrorists.

Indeed the current epidemic of suicide terrorism is directly tied to this perception of its success by terror-sponsoring groups. As its use migrated around the world even many counterterrorism experts have credited suicide terrorism with derailing the Oslo peace accords, disrupting the peacekeeping and rebuilding efforts in Afghanistan and Iraq, impacting the election results in Madrid,² and drawing world attention and concern to political issues that may otherwise have been overlooked. Whether it is effective in achieving any real political gains outside the community in which it originates, that is, whether it creates

personal communication 2005). Looking back into the ancient past, many cite the scriptural account of Sampson as one of the first suicide terrorists; when blinded and chained to pillars, he decided to use his great strength to pull the columns down, collapsing the building on himself and those surrounding him. Similarly, some experts recall the Muslim Assassins and Jewish Sicari as the first suicide terrorists; both groups carried out assassination missions that were nearly always suicidal for the person carrying it out. Also Pakistani warriors in ancient times were known to run underneath the elephants carrying advancing troops to slit the bellies of the warring beast, bringing them down on themselves and killing both their enemy and themselves in the process.

²Some argue that the Madrid bombings did not involve suicide terrorists because the attackers left their bombs and detonated them from afar; yet threatened with imminent arrest, the bombers did explode themselves.

¹I am indebted to Mia Bloom for coining this phrase, which she also uses as the title for her book *Dying to Kill: The Allure of Suicide Terror* (Columbia University Press, 2005). Suicide bombing as a strategic tactic is not a new phenomenon. In recent history, it appeared in the 1950s in Vietnam in the form of bicycle bombers who exploded themselves in cafes, killing the enemy occupiers who frequented them (Francois Gere, French counterterrorism expert,

any real power base for those who employ suicide terrorism, is still, however, debatable.

Terrorist organizations thrive because of failed political solutions between conflicting parties, and their continued existence relies on their ability to change perceptions and impact the political process in favor of their constituent groups. When a much weaker group is pitted against a larger, more powerful, better financed and militarily equipped group, suicide terrorism becomes the tactic of choice because it is seen by the weaker group as strategically both efficient and more likely to lead to desired results than any other method of violence.

Suicide terrorism is a tactic that is:

- Inexpensive. It requires relatively simple, noncostly, and easily accessible equipment. The 9/11 attacks on the World Trade Towers and Pentagon cost approximately \$400 000, the Bali bombings approximately \$20 000 (NATO Defence College, 2004).
- Highly effective. The human bomber is essentially a smart bomb, going directly to his or her target and able to make adjustments even up to the last moments before detonation to avoid detection and to maximize the amount of damage done in the attack.
- Highly lethal. Suicide terrorism operations are the most lethal of nearly all currently used terror operations, and although they make up only a small fraction of the total of terrorist operations, they kill and wound the greatest number of victims.
- Extremely horrifying. The carnage caused by human bombers almost always makes the news; hence, by targeting only a small group of civilians the terror-sponsoring group can count on the media to amplify its effects, causing horror and dread to spread throughout a much wider witnessing audience.
- Nearly impossible to prevent. Once a bomber is equipped and on the way to the target, he or she is virtually impossible to stop (unless he or she can be talked out of the mission, which is rare) because he or she can always explode him- or herself on detection (Ganor 2005).
- Difficult to trace. The bomber, if successful, is killed in the attack and, unlike in other terror acts, needs no resources or risk dedicated to an escape plan; and once killed he or she cannot be caught and interrogated later, revealing who sent him or her.
- In endless supply, if the terror group's constituent population supports the use of this tactic. The main cost of suicide terrorism is the human beings who agree to sacrifice themselves on behalf of the terrorist cause. If this pool of individuals is large, the

terror organization has a virtually endless supply of weaponry and can carry on a very strong war of attrition with a much more powerful enemy who may eventually make concessions to the terror-sponsoring group simply to end the campaign of bombings.

The Lethal Cocktail of Suicide Terrorism

Suicide terrorism originates from the confluence of four main aspects of suicide terrorism: the sponsoring group's motivations, the ideology that supports it, the individual motivations for enacting it, and the societal support for suicide terrorism. Without this confluence of factors, suicide terrorism ceases to exist (Argo, 2003; Hafez, 2004; Merari, 2003; Moghadam, 2003; Speckhard, 2005b; Speckhard and Ahkmedova, 2005). When all these factors are present, suicide terrorism becomes a tactic that can travel the world as a spark igniting and reigniting a massive fire that we can only hope to be able to extinguish before it consumes us in its flames.

Sponsoring-Groups Motivations

Organizations provide the means, methods, and group dynamic underlying suicide terrorism operations and often the ideology as well. However, terrorist ideologies should not be thought of as simple constructs of terror-sponsoring groups. They arise, in fact, from a complex mix of social and political circumstances, psychological and religious context, and interplay among the actions, sentiments, and rhetoric of terror groups, their constituency, and the perceived oppressor-enemy. When looking at the motivations on the organizational level, we must acknowledge that terror-sponsoring organizations are largely political in their motivations and resort to terrorism when other political solutions have failed and resort to suicide terrorism when a specific set of circumstances exist. Researchers of suicide terrorism know that it is nearly always used strategically by organizations and generally resorted to only when the enemy is much stronger and better equipped militarily. Likewise, it is often used in later stages of the conflict (Bloom, 2005); sometimes reflects an outbidding process for power among competing groups (Bloom, 2005); and finds a receptive base of support in areas where occupation occurs, particularly if the foreign occupier is of another religion than those occupied and is perceived as oppressive and unjust (Pape, 2005; Speckhard, 2005b; Speckhard and Ahkmedova, 2005; Speckhard and Ahkmedova, 2006b). When

these circumstances exist, suicide terrorism may be deemed an effective choice by terror-sponsoring organizations for forcing concessions from its stronger enemy and thereby achieving its political goals.

Ideologies of Suicide Terrorism – Religion and Cosmic Warfare

Currently the strongest ideology supporting suicide terrorism makes use of distorted versions of Islam. As anyone who has studied the history of warfare knows, religion is often invoked to send warriors out to battle because believing that one is dying for a higher cause is highly motivating. Nearly all major faiths have in the past been used in this way and still are. Just as nearly all nations going to war today still make use of religious rhetoric when looking for popular support and to motivate their warriors, so too do many of today's terror-sponsoring groups (consider the rhetoric of the Crusades and the just war debates carried on in the West prior to the invasions of Afghanistan and Iraq). Although the loosely affiliated Al Qaeda/global Salafi terrorist groups do not represent legitimate nation-states, they claim that they are acting in behalf of a group of beleaguered people and that they are in a war, and their ideology is aimed to motivate warriors for the battle. The difference is not so much in the use of religion to garner popular support for acts of war and to motivate warriors but in the distortions of mainline religion to justify the tactic these warriors are motivated to adopt and the targeting of innocent civilians that their ideology justifies. We see in these current jihadist ideologies promulgated over the Internet and through underground networks the promotion of suicide terrorism – claiming it as the most effective way for these groups to triumph – the manipulation and misuse of treasured religious principles valuing martyrdom on behalf of Islam to motivate foot soldiers to self-recruit themselves for suicide missions against innocent civilian targets.

The suicide terror groups' uses of religion to motivate individuals to sign up to die makes strategic sense. Any believer of any faith who is persuaded of the following will act in extraordinary ways:

- He or she is in a cosmic battle (Juergensmeyer, 2000) involving apocalyptic forces
- that will eradicate either his side or the other, hence necessitating a war of defense.
- He or she should dehumanize and even demonize his or her enemies by seeing them as the enemies of God.
- In joining the group and taking on its values and teachings, he or she has learned the mind of God

and is authorized to act in the battle by the will of God.

- The battle in which he or she is fighting is for sacred values (Atran, 2003).
- He or she may go to extraordinary means to eradicate and blot out those he or she sees as evil-doers – even innocent civilians – who he or she believes are standing in the way of and offending God's will.

It is important to state however that, even though groups that make use of distorted versions of Islam are currently highly effective in promoting this cosmic warfare ideology to endorse the tactic of suicide terrorism, this does not mean that Islam itself is the problem. If it were, we would not have seen the Liberation Tigers of Tamil Eelam (LTTE) and the Popular Front for the Liberation of Palestine (PFLP), which are mainly composed of Marxist atheists, making use of this same tactic. In those cases, they made no reference to Islam, or to religion at all, but relied on charismatic leadership, deep-seated anger over nationalistic concerns and injustices, and the hope of becoming heroes for their cause to motivate human-bombing recruits. Likewise, many cults have made similar use of non-Islamic religions to induce an apocalyptic vision of the world in their believers, who then become willing to endorse violence and even kill and die in order to bring it about; these include the Aum Shinryko, the Japanese Hindu-related cult responsible for the sarin-gas poisonings in the Tokyo metro; the People's Temple cult that followed Jim Jones, whose members made a suicide pact and killed themselves and their families, resulting in over 900 deaths; and the Army of God, the Christian-based abortion clinic bombers.

So, although Islam is currently being misused to promote suicide terrorism, it is not in itself the problem. The problem is the powerful links that terrorists groups are able to make among individual motivations to self-sacrifice, societal circumstances leading to despair and defiance, and a hijacked version of Islam that, playing on sacred scriptures, promotes human sacrifice on behalf of the group. Any mainline religion can be distorted and used to motivate for suicide terrorism by framing it as an ideology in support of self sacrifice in a cosmic war of defense for the true faith. Currently, the main ideology in use among the most active suicide terrorist groups (i.e., the loosely affiliated Al Qaeda/global Salafi and other nationalistic militant jihadist-linked groups) is a hijacked version of Islam that calls for would-be martyrs from around the world to sacrifice themselves on behalf of a worldwide or nationalist jihad.

Individual Motivations

But why would anyone answer the call? Why do most of the main terror groups in Palestine, Lebanon, Iraq, Afghanistan, Chechnya, and elsewhere state that they have an endless supply of recruits – such as the Chechen female bomber who spoke on a prepared video broadcast during the Dubrovka/Nord Ost theater takeover in Moscow, where 800 hostages were held for 3 days, stating, “Even if we are killed, thousands of our brothers and sisters will come after us ready to sacrifice themselves” (Jazeera, 2002). Certainly there must be something much more powerful behind this than simply an ideology to make an individual cross the line from normal daily life to strapping on a bomb or getting into an airplane, car, or truck intent on exploding him- or herself in the middle of a crowd of civilians. What are the factors that cause these changes to occur within a human soul?

Although the answer is multifaceted and impossible to answer in this short article, our research speaking to bombers, would-be bombers, senders, the family members and close acquaintances of bombers, and their hostages points to two main motivational sets (Speckhard, 2004, 2005b, 2005c, April 2005; Speckhard & Ahkmedova, 2005, 2006; Speckhard & Ahkmedova, 2004, 2006a, 2006b; Speckhard, Tarabrina, Krasnov, & Ahkmedova, 2004; Speckhard, Tarabrina, Krasnov, & Mufel, 2005a, 2005b): trauma-based motivations and alienation-based motivations.

Trauma-Based Motivations

The first motivational set is a trauma-based and occurs within zones of active conflict. It is often nationalistic, viewed in terms of self and community defense, and expressive regarding meting out justice to the perceived enemy-occupier, and it often includes acts of revenge. The individuals motivated within this set have witnessed firsthand and over the television their neighbors, family members, and loved ones being killed by what they view as an occupying force. Many have grown up witnessing countless acts of violence and, as a result, have not developed normally and often suffer from posttraumatic stress and dissociative disorders. Many have lost jobs, educational opportunities, been humiliated, and often struggle for basic daily needs and security. Although the majority of traumatized individuals in conflict zones will not become suicide bombers even if invited to do so, an extremely small group will become vulnerable to terrorist ideologies that promote this tactic. Feeling constantly agitated by traumatic flashbacks; unable to avoid daily reminders of

their traumatic losses; and feeling in constant danger, bereaved, angry, and impotent, these individuals ultimately become so dissociative (i.e., separated from normal thoughts, perceptions, and emotions) and emotionally numb that they often refer to themselves as “already dead.” Actually, for them dying is no longer a feared outcome; they have already psychologically and emotionally numbed themselves to human suffering, yet it keeps mercilessly and painfully intruding into their thoughts, so death may seem as a welcome release. Embracing it and exerting some control over when and how it occurs is sadly welcomed by these traumatized individuals.

In response to threat, a normal person reacts in a fight-or-flight response and will only move into dissociative defenses (i.e., shutting down the normal features of consciousness such as emotions, logic, and memory and sometimes physically freezing as well) when the threat becomes overwhelmingly horrific, terrifying, and life-threatening. When this distinction was explained to him, Al Aqsa Martyrs’ Brigade sender of suicide bombers Zecharia Zubeidi explained, the individuals he equips to become human bombs are, according to his observations, caught inflexibly over long periods of time in a dissociative mode. He stated that, whereas combatants are flexible in their responses to violent conflict, these victims of the conflict are not. “They are completely different than us [fighters]. They have only one decision. We have many options. The thought of running away is always available. We can go and shoot.” In contrast, he described the martyrs as locked into an inflexible dissociative mode caused by traumatic stress and the one decision that comes from it. He stated, “They get flashbacks all the time and for them death is a mercy. . . . For the martyr all the cells in his mind are dead except for one.” According to Zubeidi, suicide bombers are in too much psychic pain to find another way to cope and become totally fixated on carrying out what they view as acts of community defense, expressions of pain, and enacting justice in response to “all that they have seen.” Explaining their psychological inflexibility in reference to his own dissociative states, which occur from time to time (also in response to traumatic experience), he stated, “When I feel this way I stay there one or two hours, but that one [a bomber], after all that he has observed there is only that one thing [i.e., to end his life on behalf of the community].”

Suicide bombers are often as well or better educated and less poor than their peers (Atran, 2004; Merari, 2003), and in other circumstances they might have been leaders in their communities. They are acutely sensitive to their own suffering and

that of those around them and wish to make a difference, but, similar to normally depressed and suicidal people, they see only very limited avenues of action. They want to escape their psychic pain but to do so honorably and to use their lives – even if it means dying – to help their communities. They are uniquely vulnerable to an ideology that promises that they will be heroes for the cause and that they can make a difference in the sociopolitical situation faced by their communities. They believe that their deaths are only a doorway to a better place and that by dying in self-sacrifice they can change things both now and in the afterlife, reuniting with those who have gone before and later bringing with them relatives who they left behind. Vulnerable and in pain, they succumb to an ideology that seduces them into sacrificing themselves for what they believe is a greater cause. Just like us, they hope for a more just world in which human dignity and rights will be upheld; however, unlike us, they have been deluded into believing that their acts of killing innocent civilians might bring this into being and for this they sacrifice themselves.

Alienation, Marginalization, Loss of Identity, Secondary Traumatization, and Desire for Life Meaningfulness, Belonging, and Heroism

The second motivational set involves actors not living in conflict zones and is more complex. Whereas we might understand an individual who has seen his or her family member killed in front of his or her eyes and feels his or her country has been occupied seeking revenge, we must question what can possibly motivate Europeans, Turks, Moroccans, Uzbeks, and others join such groups ultimately agreeing to die in order to kill others? In their cases, the main motivational set appears to involve vulnerable actors who are exposed through kin and friendship groups (Sageman, 2004) or through the Internet and informal recruiting to other individuals within a terror network.³ In their cases, these individuals are often marginalized, frustrated, and without hope in their societies. In Europe, they are often first-, second-, or third-generation immigrants or converts to Islam who feel deep sympathy and even kinship (i.e., as Muslim brothers) for those in conflict zones. Within the migrant community, there is often a deep sense of alienation and no secure sense of identity and belonging in either their country of origin and, more importantly, their host culture. Facing discrimination, often well educated

but facing poor job prospects, lacking positive identity and a sense of life's meaning, and having little else to make of themselves, once they are exposed to terrorist ideologies they are attracted to the appeal to become heroes for a cause.

In these cases, the sponsoring organization nearly always makes use of five powerful motivators. The first two are the ideas of belonging and identity – belonging to an important cause and group – and of taking on a heroic identity. The third is the use of pictures and graphic video footage of conflict zones that are shown to the potential recruit and interpreted as atrocities against innocent victims – mainly featuring Chechen and Palestinian suffering, but now also featuring footage and references to the US coalition's "War on Terrorism" in both Iraq and Afghanistan. Just as relief organizations in our societies often uses pictures and video footage of human suffering to motivate us to give to worthy causes, these organizations do the same, playing on the emotional reactions of their audiences to find the individuals vulnerable enough to respond to their calls to action.

In the European case, where distorted Islamic ideologies are being used, often those individuals who become terrorist recruits are sensitive and care about the conflicts they learn about but are not able to read in Arabic and fall prey to teachers who tell them that they know and can interpret the Koran for them and teach them the proper Islamic response to address such suffering. This is not to say they are simple minded; quite the contrary, often it is the well-educated and sensitive individuals who read the news and care about the world and who would have been leaders if they felt they had a way of participating in their society and its political discourse. Frustrated by their lack of opportunities to help others in need and needing a meaningful role and identity, they find answers in terrorist groups.

Fourth and fifth powerful motivators are the ideas often taken from religion that one ought to sacrifice in behalf of the brotherhood of the believers. In this manner the ideas of fictive kin (Atran, 2003) and martyrdom are instilled. The individuals who respond to such calls to action are called on to depart from the frustrations of this life, reject the society that has marginalized or frustrated them, and join a group following a path that promises eternal rewards. Suddenly the individual who was previously frustrated, feeling worthless, and had little hope feels a sense of belonging, a firm identity and purpose in what will soon turn out to be a foreshortened life.

The words of a disillusioned radical (Speckhard, 2005d) living in Brussels, Belgium, explain how he was radicalized and then found his way out of it.

³In Brussels, we have found that there are Internet cafes where, if one logs on for a half hour or so, pop up ads appear inviting one to join the worldwide jihad.

This young man (age 24) was adopted from Rwanda by white Belgium parents. Growing up as the only black in his community, he was alienated and confused about his identity. In search for his African roots, he found Islam, converted at age 15, and started attending a radical mosque, where he fell under the influence of extremist militant wahhabist teachers. "If you say to yourself this thing is God's will, you have to do it. It's simple, if you can't read in Arabic and people tell you that you cannot understand and you have to do it. I tried very sincerely to do so. I followed everything, the prayer schedule, eating and way of drinking all in the Sunnah. But there are also ideas about jihad. At age nineteen I was ready to go to Lebanon and fight for my brother Palestinian. I didn't know politics but I had an idea we had some Muslim community, our brothers that we must defend."

Speaking about how he became ready to become a martyr, he explained,

When I went to Morocco with my wife to her mother's house I saw Al Manar – Lebanon TV. They have a way to mix religion and politics. I can understand it because there is a true crisis in Palestine. . . . What I saw on the television was two Israeli soldiers taking big stones and breaking the bones of a Palestinian man, breaking his arm bones, his shoulders, all the bones in his hands, all the bones in his feet, his ribs, smashing them with a big rock. I'm sure they killed him or left him to die. I couldn't understand all of the Arabic (he was beginning to learn Arabic at this time) but I didn't need language to understand – it was all there in the pictures. Imagine people see that in the morning, get breakfast and see that on their television. When you see that you feel there is a unity of Muslim people. I decided to go there. I was completely crazy. I had a wife and baby but I thought I would go anyway.

Thankfully, this young man found his way out of the radical groups by studying Arabic and religion intensively until he found his own answers, independent of the militant teachers he had fallen under. Looking back at how close he came to going to be a martyr, he explained, "At that time I was a believing radical. For a radical you can die and kill for God no problem. I can die or be killed at anytime. I knew people who went to Afghanistan as bombers, the people who killed Mousad. To get the connections to go, here in Brussels, is no problem." Reflecting on how he got out, he explained, "The problem is you see all the people, politics, everything – you see through the Koran and it's your perspective." Similarly, he recalled that at that time "I was completely lost" and reflected that it was difficult to question what was being taught if you did not learn Arabic. "The difference between me [having left the radical groups] and the others is my studies."

Adopting a Terrorist Ideology as Psychological First Aid

In both motivational sets, the ideology of the terror-sponsoring group is acting as psychological first aid for the victim of other grievances. This psychological first aid is, of course, short-lived – as is its victim. Yet we see a powerful transformation take place in the human bomber who, seeing no way to change his or her circumstances, moves from a stance of a powerless victim of societal forces to becoming an actor in a worldwide or nationalistic drama that he or she has been persuaded might bring about a more just and dignified existence for those left behind. In this way, a marriage occurs between the terror-promoting ideology and the individual's psychosocial vulnerabilities emanating from traumatic and bereavement experiences in conflict zones and from marginalizing and frustrating circumstances in nonconflict zones. When this marriage occurs, all that is left is for the individual to believe that there is some significant portion of society that supports his or her stepping out onto this path (it may be the group that recruits him), which enables him to take the final steps to martyrdom. This is when societal support for suicide terrorism plays an important role in putting a martyr on the path to becoming a human bomb.

Societal Support for Suicide Terrorism

When a society deplores violence as an answer to violence and terrorism as an answer to social problems, it is unlikely that ideologies supporting suicide terrorism will resonate strongly within more than extremely limited groups of vulnerable individuals. However, when a society or significant elements of it begins to embrace an ideology in support of suicide terrorism, then these groups of potential recruits will expand exponentially. We witnessed this when a cult of martyrdom sprang up among Palestinians during the second Intifada and made their pool of potential recruits seemingly endless.

How does this occur? Again, it is a confluence of factors. When a society is so offended and even traumatized by daily living circumstances as a result of war, conflict, human rights violations, marginalization, frustrations, and daily humiliations and many individuals feel powerless to change these assaults to human dignity, the society can begin to support terrorist ideologies, especially those that espouse familiar and valued religious ideals, believing that terror acts may bring about change. In this case, the society begins to indoctrinate its children in support of suicide terror. Posters, songs, and videos may become prevalent throughout the society in support of

martyrdom (i.e., suicide terrorism), and the society as a whole may begin to resonate with the aims and ideology of the terror-sponsoring group.

It is most important that we avoid this when considering the fight against suicide terrorism. There will likely always be fringe groups that promote dying to kill; there will also always be individuals who are vulnerable to recruitment by these groups. However, we unwittingly create the circumstances in which the pool of recruits expands exponentially when we fail to address the societal factors leading to individual vulnerability and the societal support that make these groups impossible to extinguish and allows them to self-replenish faster than we can stop them. In these cases, their pool of recruits becomes so large that the terror groups can go on forever. Likewise, we must begin to address and take apart the rhetoric of terror-sponsoring organizations – addressing their ideologies by engaging with them in a discourse that can perhaps lead to more, instead of fewer, people believing that political solutions do exist and terror acts are neither necessary nor useful in bringing about a just, moral, and dignified existence.

As for the use of a hijacked version of Islam in the majority of the most current cases of suicide bombing, we must acknowledge two things. First, Islam is a religion that has always valued the struggle for three fundamental values: justice, morality, and human dignity. It is only natural that, when a terror group is hoping to motivate recruits, it appeals through Islamic traditions for recruits to take action on behalf of these fundamental values (especially if it can argue that recruits are acting in defense of self and community). Indeed, this idea of defense of self and community has been the basis of nearly all fatwas in support of martyrdom (i.e., suicide missions).

Second, a majority of the world's Islamic populations live under corrupt and autocratic regimes and face numerous human rights violations, territorial occupations, and discrimination; hence, there are many political reasons that Islamic people might gravitate to a terrorist ideology that shares with them the political goals of fighting for freedom and human dignity. Religion is simply the vehicle for uniting them and giving them the courage to fight (in whatever mistaken or brutal ways they chose) for the political goals they share. When we mistakenly believe that Islam itself is the problem and begin to assault deeply valued religious traditions and beliefs, we only fuel the fires of the terrorism ideologies currently in vogue.

There is also a contagion effect that we must consider, which occurs even with normal suicide – those who are in the family and friendship network of a suicide bomber are often so deeply affected by the act

that they too begin to consider acting similarly. We found countless examples of radicalization proceeding through close friendship and relatives networks, as have other authors (Sageman, 2004). Thus, radicalization can increase geometrically once it gets going.

Suicide terrorism is a complex psychosocial and political issue and demands thoughtful, just, and carefully carried out responses to bring an end to its continued and increasing use to influence worldwide politics.

Acknowledgments

In recent years, I have had the opportunity with my colleagues to interview incarcerated suicide terrorists; potential recruits for human bombers; senders of suicide terrorists; members of terrorists groups; and, perhaps most important, family members, hostages, and close associates of accomplished bombers to ask about the bombers, the events, and the influences that motivated these individuals to choose to die in this way and thereby to construct a psychological autopsy of them. These interviews concerned Chechen, Palestinian, Lebanese, Uzbeki, and Moroccan suicide terrorism and radicalization of groups in Europe and took place in Chechnya, North Ossetia, Russia, Belarus, Uzbekistan, Lebanon, Morocco, Palestine, Israel, the Netherlands, France, United Kingdom, and Belgium. I especially thank Khapta Akhmedova, Mokhtar Benabdallaoui, Valery Krasnov, Natalia Mufel, Yoram Schweitzer, and Nadejda Tarabrina for helping me in conducting the interviews and my students Ken Reidy and Valentijn Vanrompay, who accompanied me on trips to the Palestinian territories. I am also indebted to Scott Atran, Nichole Argo, Mia Bloom, John Esposito, Rohan Gunaratna, Bruce Hoffman, Mark Juergensmeyer, Assaf Moghadam, Cerwyn Moore, Jerrold Post, Marc Sageman, Jessica Stern, Andrew Silke, Michael Taarnby, Reuven Paz, John Horgan, and many others who have contributed to this field of research and helped me refine my technique and theory and have added to my understanding of this complex phenomena through conversations, critiques of my work, and correspondence.

Introduction

A Model for Understanding Suicidal Behavior

Stressors: Triggers for Suicidal Behavior

Risk Factors Influencing the Threshold for Suicidal Behavior

Summary

Glossary

<i>5-Hydroxyindoleacetic acid (5-HIAA)</i>	A metabolite of serotonin.
<i>Cerebrospinal fluid 5-hydroxyindoleacetic acid (CSF 5-HIAA)</i>	The concentration of 5-HIAA found in the cerebrospinal fluid. The concentration of 5-HIAA in the cerebrospinal fluid is considered a reflection of serotonergic function in the central nervous system.
<i>Major depression</i>	A temporary or chronic mental disorder characterized by the occurrence of five of the following symptoms during a 2-week period or longer: feelings of sadness, inability to enjoy things, sleep disturbance, appetite disturbance, psychomotor changes, fatigue, difficulty concentrating, and suicidal ideas.
<i>Model for understanding suicidal behavior</i>	An explanation of how suicide risk factors contribute to suicidal behavior by creating a predisposition to suicidal behavior (lowering the threshold for suicidal acts) or by acting as triggers or stressors precipitating suicidal acts.
<i>Psychosis</i>	A temporary or chronic mental condition characterized by an inability to distinguish between reality and nonreality.
<i>Serotonin</i>	A neurotransmitter with multiple effects throughout the brain and with a role in a variety of psychiatric disorders and

Stress

symptoms, including depression, anxiety, aggression, and suicidal behavior.

A force that disrupts the equilibrium or normal functioning of an individual's mental or physical state. Different types of stressors may precipitate suicidal behavior.

Suicide

Self-inflicted death committed by an individual with the intention to end his or her life.

This article describes how stressors interact with a low threshold for acting on suicidal ideas. The types of stress that may lead to suicidal behavior are discussed, and factors influencing the threshold for suicidal behavior are described. Stressors that contribute to suicidal behavior include negative events, social conflict, acute psychiatric conditions, acute intoxication, and contagion. Risk factors that lower the threshold for suicidal behavior include family history of suicidal behavior, low serotonergic functioning, comorbid psychiatric conditions, dysfunction of the stress-reactivity hormonal system, marital isolation, early parental loss, and a history of sexual or physical abuse. Factors that raise the threshold for suicidal behavior include religious affiliation, moral constraints, concerns about social disapproval, and feelings of responsibility toward family. An understanding of the risk factors for suicidal behavior and stressors is crucial in developing methods for the prevention of suicide attempts and completion. Because it is a combination of these psychiatric, biological, and environmental risk factors that ultimately leads to an individual's suicide, interventions that address both the role of stressors and raise the threshold for acting on suicidal impulses are critical to prevention.

Introduction

Suicide is a self-inflicted death by an individual with the intention of ending his or her life. As the eleventh leading cause of death in the United States, it accounts for approximately 30 000 deaths a year in the United States and almost 1 million deaths worldwide. In the United States, suicide is the third leading cause of death in people ages 15–24 years and the second leading cause of death in those ages 24–35 years. The World Health Organization has noted a 60% increase in suicide deaths in the past 45 years. Although the actual number of suicide attempts is more difficult to quantify, it is estimated to be 10–20 times that of completed suicides.

Psychiatric, biological, and environmental factors contribute to suicidal behavior and ultimately to suicide completion. Among environmental contributors, stress has long been recognized as having a role in the timing of suicide. However, stress may also be mediated by psychiatric or biological factors. In addition, stress alone, although important, is not a sufficient condition for suicidal behavior. Suicidal behavior also requires a vulnerability for acting on such impulses. Thus, risk factors for suicide can be understood using a model that integrates the role of stress and the threshold for acting on the resulting suicidal impulse.

A Model for Understanding Suicidal Behavior

We have described a model in which suicidal behavior is the outcome of the interaction between an individual's threshold for suicidal acts and stressors that serve as triggers for suicidal behavior. In this model, which is illustrated in [Figure 1](#), the threshold is trait-related and refers to the propensity for suicidal behavior. In contrast, stressors, which may be considered state-related, are triggers that determine the timing and contribute to the probability of suicidal acts. Consequently, risk factors that contribute to suicidal behavior may be categorized according to whether they affect the threshold or act as stressors.

Stressors: Triggers for Suicidal Behavior

Stressors may be environmental, behavioral, biological, or a combination of these, as listed in [Table 1](#).

Environmental Stressors

Environmental triggers can be categorized as negative events or as contagion. Negative events may include financial difficulties, interpersonal loss (death of a family member or a loved one), loss of property, conflict with parents, or other interpersonal conflict. Contagion refers to the effects of suicides in the community on an individual's decision to commit suicide. These triggers may contribute to the timing of the suicidal act.

Negative events, specifically the loss or lack of a significant relationship, have been suggested to play a key role in the deaths of (1) suicide victims without mental health care, (2) suicide victims with alcohol abuse, (3) suicide victims with personality disorders, and (4) suicide victims with mood disorders. In addition, suicide is associated with financial troubles, homelessness, and job problems. The number of adverse life events appears to play a role as well. However, stressors or negative events related to suicide may vary depending on the culture studied. Most studies published in English have been conducted in Western cultures. Similarities regarding the precipitants of suicide in Eastern and Western cultures exist, such as the number of adverse life events; the presence of severe, acute stress at the time of death; high chronic stress in the year before death; and poor quality of life in the month before death. Yet differences in terms of the type of events that may precipitate suicide have been reported. In China, for example, loss of face, described as an unexpected insult to one's reputation, is a stressor associated with suicide not generally observed in Western cultures. As such, it appears that in different cultures the sensitivity to particular environmental stressors differs.

Figure 1 The diathesis–stress model for understanding suicidal behavior.

Table 1 A model for understanding suicidal behavior

	<i>Stressors precipitating suicidal behavior</i>	<i>Factors affecting the threshold for acting on suicidal ideation</i>
Environmental	Negative events (social, financial, or family crisis) Contagion	Marital isolation Lack of religious affiliation Low self-esteem Fewer perceived responsibilities toward family Fewer perceived reasons for living Alcohol or substance abuse
Behavioral	Judicial environment Acute substance intoxication	
Biological	Major psychiatric episode Acute substance intoxication	Genetic and familial factors Low serotonergic activity (aggression) Stress response (childhood history of physical and sexual abuse) Comorbidity (alcohol or substance abuse, cluster B personality disorder, posttraumatic stress disorder)

It is possible that negative events lead to suicide at least in part by disrupting the person's social support network; this network often plays a major role in suicide prevention by providing supervision and emotional support. For example, loss of a loved one is a negative event that leads to an immediate decrease in social support, and this can trigger suicidal behavior. Similarly, social support may be acutely lowered when there is conflict with family and can thereby trigger suicidal acts. Consistent with this idea, the social networks that attempters have seem to be weaker than those of nonattempters, as measured by marital status, living alone, interactions with family members, frequency of recent moves, and the number of close friends.

Another important environmental trigger is contagion, also known as the Werther effect, which was named by Philips in 1974 after Goethe's *The Sorrows of Young Werther*. The Werther effect has been documented as a meaningful contributor to suicidal behavior in both adolescent populations and older populations. Recent outbreaks of suicide in adolescent and elderly populations have raised concerns about media coverage of suicides and the potential for precipitating more suicidal acts within communities. Presumably, individuals with a lower threshold for acting on suicidal thoughts are more likely to act on them after learning of a suicide or an assisted suicide on television or in the newspaper. Moreover, the judicial environment may affect the risk for suicidal behavior in contagion situations by changing public attitudes about the acceptability of suicide. Although there is limited data available, it is possible that the extensive media coverage of physician-assisted suicide and its legalization in one state of the United States, as well as in some European countries, has increased the rate of suicide across diagnoses, including major depression, and specifically in those who are chronically ill and depressed. In

fact, physician-assisted suicides and euthanasia contribute to significant underreporting of suicides (as much as 20%) in countries such as the Netherlands, where these procedures are often not reported.

Thus, environmental factors or stressors that play a role in suicidal behavior include the disruption of social support networks, negative events, and interpersonal conflict as well as the altering of perceptions about the acceptability of suicide. These stressors are not causal, however, because the majority of individuals exposed to them do not commit suicide. Nonetheless, they may contribute to the timing and occurrence of suicidal acts in vulnerable people.

Biological and Psychiatric Stressors

Acute psychiatric illness Although depression or psychosis are not often conceptualized as stressors, it is useful to consider them as such because suicide rarely occurs in the absence of a major psychiatric disorder. The rate of mental illness in suicide victims varies from 90% in Western cultures to 60% in Eastern ones. However, even those subjects who do not meet criteria for a major psychiatric disorder seem to have some form of psychopathology. The most common mental disorders in suicide victims are depression and substance abuse, particularly alcoholism.

However, psychiatric illness alone is not sufficient to trigger suicidal behavior. Between 2 and 15% of subjects who suffer from unipolar depression ultimately commit suicide. Schizophrenia also carries a high risk of 10–15%. In bipolar disorder, the risk for suicide is generally considered to be approximately 19%; however, whereas some propose that it is nearly 50%, others question whether even 19% is an overestimate. Nonetheless, despite the high rate of suicide associated with these psychiatric conditions, most patients with these conditions do not commit suicide or even attempt suicide. Thus, the presence of a single stressor such as a psychiatric condition appears to

be a necessary, but not sufficient, cause for suicidal behavior.

Acute intoxication Substance and alcohol abuse greatly increase the risk of suicide, an effect that is especially pronounced in youth suicide. Acute substance intoxication can be considered a trigger associated with suicidal behavior. In fact, a recent review of acute alcohol use and suicidal behavior noted that 37% of completed suicides and 40% of attempted suicides involved acute alcohol use. Moreover, acute alcohol use was more prevalent among those who used violent methods of suicide such as self-immolation or gunshot.

To the extent that some individuals respond to environmental stress by using substances, acute intoxication may mediate suicidal responses to stress. The consequences of acute intoxication appear to be biological and behavioral in nature. The biological consequences of acute intoxication with alcohol include, for example, an acute increase of serotonin release, although the long-term consequence is lower serotonin function. In addition, the disinhibiting behavioral effects of intoxication may also play an important role in its association with suicidal behavior. Individuals may be more likely to act on a suicidal impulse when acutely intoxicated than when sober. Thus, acute alcohol intoxication has a complex relationship to suicidal acts.

Risk Factors Influencing the Threshold for Suicidal Behavior

Evidence for the existence of a threshold for suicidal behavior comes from two general findings. First, suicidal behavior manifests early in the course of illness, suggesting that individuals with a vulnerability for this behavior (lower threshold) are likely to express it early in the face of a stressor such as a depressive episode. Second, suicidal behavior runs in families independently of familial risk for mood disorders. Together, these factors suggest that the vulnerability to suicidal acts is not merely related to the presence of a mood disorder or to demoralization secondary to prolonged illness. Rather, suicidal behavior relates to a threshold, predisposition, or diathesis toward acting on suicidal urges. This threshold for suicidal behavior is influenced by risk factors that may be categorized as familial/genetic, biological, or environmental, as listed in [Table 1](#).

Familial/Genetic Influences on the Threshold for Suicidal Behavior

Evidence for the presence of genetic risk factors include the presence of a family history of suicide.

Although this risk factor could be thought of as facilitating suicidal behavior due to identification or contagion, it includes a genetic component as well. Adoption studies have found that, independent of the transmission of a major psychiatric disorder, adoptees who commit suicide have a sixfold higher rate of suicide among their biological relatives than do matched adoptees who do not complete suicide (None of the adopting relatives committed suicide.) Moreover, there appears to be greater concordance for suicide in monozygotic than in dizygotic twins. Other evidence for the genetic component of suicide is that the familial transmission of suicide risk to offspring appears to be independent of the transmission of psychiatric conditions. A study of Old Order Amish families has shown that family loading for mood disorders alone is not predictive of completed suicide. Rather, individuals with both a mood disorder and a family history of suicide have an increased risk for suicide.

Most genetics studies of suicidal behavior have focused on seven genes: the serotonin transporter (SERT), tryptophan hydroxylase (TPH) 1 and 2, three serotonin receptors (5-HTR1A, 5-HTR2A, and 5-HTR1B), and the monoamine oxidase promoter (MAOA), all of which are key proteins in the maintenance of serotonin function. Although there are no clear findings, the following are most promising:

1. The SERT promoter gene has two polymorphisms or variants, a short and a long form. The short form has been associated with suicidal behavior in different subpopulations, such as violent attempters and female suicide attempters. In a recent meta-analysis, suicidal behavior was reported to be more common in those with the short variant of the SERT promoter gene (OR = 1.17, CI 1.04–1.32; $p = 0.009$). Moreover, the short form has been reported to have an interaction with current life events, making those with this variant vulnerable to suicidal behavior when exposed to stress.
2. The 5-HTR1A gene encodes the 5-HT_{1A} receptor, which in depressed suicide victims has been found to have altered binding in the ventral prefrontal cortex, the region of the brain involved in decision making and restraint, among other functions.
3. The 5-HTR1B gene, which encodes the 5HT_{1B} receptor, appears to be related to impulsivity and aggressive behavior. This gene has two identified variants, both associated with 20% fewer receptors in the postmortem brain, although these variants were found at the same frequency in suicide and control subjects.
4. A low expressing version of the MAO gene has been reported to interact with exposure to

childhood abuse, resulting in aggression in adult males and indicating that the effect of this gene is only manifested if there are negative environmental conditions or, in other words, is dependent on a gene-environment interaction.

Thus, genetic and familial contributions to the diathesis for suicidal behavior require further inquiry but hold promise in the elucidation of suicide risk in individuals who carry the relevant variants of these genes.

Neurobiological Influences on the Threshold for Suicidal Behavior

The relationship of abnormal monoamine function to suicide risk has been studied for over 30 years. CSF 5HIAA is a metabolite of serotonin and its concentration in the cerebrospinal fluid (CSF) is considered a reflection of serotonergic function in the central nervous system (CNS). Patients with major depression who have made suicide attempts have lower levels of 5-HIAA in their CSF compared to depressed patients who do not have a history of suicide attempts. The reduction in CSF 5-HIAA appears to be more pronounced in depressed patients making planned, highly lethal attempts that more closely resemble failed suicide. Furthermore, CSF 5-HIAA correlates with characteristics of the most lethal attempt in the patient's lifetime, even when the suicide attempt is not temporally close to CSF measurements. In addition, CSF 5-HIAA seems to predict the risk of future suicide. These findings, together with those from animal studies in which the heritability and stability of CSF 5-HIAA on test-retest has been demonstrated, suggest that serotonergic dysfunction is trait-related and thus can reasonably be considered a factor that lowers the threshold for acting on suicidal thoughts.

Other measures of serotonergic function also indicate decreased serotonergic function in the CNS of suicide attempters. Fenfluramine has been widely used as a serotonin-releasing agent. Its effects on serotonin include reuptake inhibition, release from presynaptic storage granules, and possibly direct stimulation of postsynaptic receptors. We have reported that a fenfluramine challenge test elicited a lower serotonin-mediated prolactin response in patients with a major depressive episode who had a lifetime history of high-lethality suicide attempts compared with depressed patients who had a lifetime history of only low-lethality attempts. Moreover, using positron emission tomography and radioactively tagged glucose, we have reported that high-lethality suicide attempters exhibit low metabolism in the prefrontal cortex, the brain area associated with decision making and restraint. They also show impaired serotonergic responsivity. Both of these

abnormalities are proportional to the lethality of their suicide attempt and are related to suicide intent and impulsivity and thus may influence lethality via these parameters. In addition, the postmortem examination of brains from suicide victims found reduced binding to the serotonin transporter sites, which was especially pronounced in the ventral and dorsal prefrontal cortex. The increased binding or number of postsynaptic 5-HT_{1A} and 5-HT_{2A} receptors in prefrontal cortex, postulated to reflect an accommodation to low serotonin, has been reported in most studies as well. Studies of brain stem, from which CNS serotonin neurons emanate, have found reduced concentrations of serotonin or 5-HIAA in suicide victims. Together, these findings suggest that serotonin dysfunction in the CNS is associated with severe and lethal suicidal behavior.

Lower serotonergic functioning may have other effects on suicidal behavior as well and may mediate the association between suicide and behaviors such as aggression and alcoholism. Among depressed individuals, those who have made suicide attempts tend to be more aggressive. Several studies show that in humans and in nonhuman primates, aggression is linked to low serotonin function. Similarly, the biological underpinnings of the predisposition to abusing alcohol, including a low serotonin function and lower CSF 5-HIAA in alcoholics during abstinence compared to immediately after the discontinuation of drinking, have been shown. Thus, individuals predisposed to alcoholism or aggression may have biological parameters, such as low central serotonergic functioning, that are also associated with suicidal behavior.

In summary, serotonergic dysfunction may influence the threshold for both attempted and completed suicide. Moreover, serotonergic function may be a mechanism whereby genetic factors influence the suicide threshold. Clearly, the relationship among genetic endowment, suicide, and serotonin functioning needs further study.

Stress Response and Suicidal Behavior

Childhood physical and sexual abuse has been associated with suicidal behavior. Those who experience corporal punishment in adolescence are reported to be at increased risk of depressive symptoms, suicidal ideation, and alcohol abuse. Suicidal ideation increases markedly with the frequency of adolescent corporal punishment for both males and females. In fact, adolescent suicide attempters are three to six times more likely than controls to have had contact with the social services department. They also commonly had notations in their chart about child abuse. In a college sample, 16% of men and 24% of women

reported sexual abuse as children. Such a history predicted depression, chronic self-destructiveness, suicidal ideation and attempts, self-mutilation, and substance abuse. The younger the person was at time of first abuse, the higher the number of suicide attempts reported. Similarly, in a sample of depressed individuals, suicide attempters were more likely to have experienced sexual abuse themselves as children, and their offspring were also at increased risk for being sexually abused and for being suicide attempters, than were depressed individuals who were not suicide attempters. These findings support the link between childhood abuse and subsequent suicidal behavior.

Childhood physical and sexual abuse has been linked to abnormalities in the stress response as mediated by the hypothalamic-pituitary-adrenal (HPA) axis. The HPA axis, with its intricate two-way interaction with the serotonergic system, has been proposed to play a key role in the correlation between early stress exposure and later impulsivity, aggression, and suicidal behavior. Indeed, suicidal behavior seems to be related to hyperactivity of the HPA axis. Among depressed individuals, those with a hyperactive HPA axis, as demonstrated by an inability to suppress cortisol in the face of external steroid administration (dexamethasone suppression test), have been reported to have a ninefold elevation in risk for suicide. Moreover, suicide victims have larger adrenal glands, which produce stress hormones and low prefrontal cortex corticotropin releasing hormone binding, consistent with a hyperactive HPA axis.

Influence of the Presence of Multiple Psychiatric Diagnoses on the Threshold

Comorbid conditions that increase the risk for attempted suicide include alcohol abuse, substance abuse, posttraumatic stress disorder, and cluster B personality disorders. In depressed inpatients, these conditions are more common among suicide attempters.

Studies have suggested that when alcoholism and depression are comorbid, suicide attempt risk is greatly increased, even when the presence of an antisocial personality disorder or other personality disorders are controlled for. Furthermore, depressed alcoholics usually report more suicidal ideation than nonalcoholic depressed patients, even when the severity of other depressive symptoms is similar. Apart from the biological pathways previously noted, other mechanisms may mediate the relationship between alcohol and suicide. For example, alcoholism may lead to unemployment, financial problems, and interpersonal problems. Psychologically, it may increase loneliness and aggression and it may inhibit coping

mechanisms, all of which may lower the threshold for suicidal behavior.

Suicide attempts are also reported to be more common in depressed patients with comorbid borderline personality disorder (BPD) than in depressed patients without BPD. Moreover, subjects with major depression and comorbid borderline personality disorder are more likely to make multiple suicide attempts, and the attempts are no less medically damaging than those made by patients with major depression alone. Thus, the potential lethality of suicide attempts in patients with comorbid disorders and/or BPD should not be underestimated.

Posttraumatic stress disorder (PTSD) is frequently comorbid with depression, and when they co-occur the risk for suicidal behavior is enhanced. The relationship between PTSD and suicidal behavior appears to be mediated by the presence of cluster B personality disorder (CBPD), with both PTSD and CBPD arising as a result of earlier traumatic experiences. The assessment and treatment of comorbid conditions such as PTSD and CBPD in the context of depression may contribute to the reduction of suicide risk in this vulnerable population.

Environmental and Psychological Influences on the Threshold for Suicidal Behavior

There are environmental and psychological effects on the threshold for suicidal behavior. Environmental conditions that lower social support, such as marital isolation or living alone, are associated with suicide risk. Indeed, married women have a lower rate of completed suicide than women who are not married. In the same vein, an association between committing suicide in the context of a major affective disorder and not living with a child under the age of 18 has been reported.

However, there are clinical variables that increase the threshold for suicide attempts. These include religious or moral constraints, concerns about social disapproval, and coping and survival skills. In particular, religious affiliation seems to be associated with less suicidal behavior in depressed inpatients, and this protective effect may be mediated through moral objections to suicide and feelings of responsibility toward family. In fact, for a woman, the likelihood of completed suicide decreases as the number of children she has increases.

A variable not easily classified as influencing either threshold or trigger is low self-esteem. Although low self-esteem can be an enduring trait, it is also a symptom of depression that can be exacerbated during depressive episodes. In patients with recurrent major depressive disorder without comorbid personality disorders, those who reported feeling like a failure

were significantly more likely to have made a suicide attempt than those not reporting such feelings. In agreement with this finding, we have found that a factor of the Beck Depression Inventory that captures self-blame is associated with a history of suicidal behavior. Thus, low self-esteem may decrease the threshold for acting on suicidal thoughts in general, and its effect may be magnified during acute episodes of depression.

In summary, environmental factors related to social support and psychological attitudes, such as self-esteem or moral constraints against suicidal behavior, are important contributors to the threshold for suicide.

Summary

Risk factors can facilitate suicide by either acting as stressors or lowering the threshold for suicide. These stressors may be environmental, biological, or psychiatric in nature. Environmental stressors include negative events and contagion. Psychiatric stressors often have biological underpinnings, and acute psychiatric illness is a prominent stressor that is present in 60–90% of suicides. Acute intoxication also increases the risk of suicidal behavior by causing changes in serotonergic function and by disinhibiting the individual, making it more likely that he or she will act on suicidal impulses. These stressors act as triggers and precipitate suicidal acts.

However, whether psychiatric, environmental, or biological, stressors do not act alone in influencing suicidal behavior. Other risk factors influence suicidal behavior as well by lowering an individual's threshold for acting on suicidal ideation. Risk factors that lower the threshold for suicide can also be distinguished by three major categories: biological, psychiatric, and environmental.

Many studies of familial transmission of suicidal behavior have suggested that there is a genetic component to suicidal behavior. The strongest findings are related to the serotonin transporter gene (SERT), although there are promising results for other serotonin-related genes. Neurochemical risk factors such as lower CSF 5-HIAA levels and hyperactivity of the HPA axis are also associated with suicidal behavior and appear to be biochemical traits. These biological factors may potentially become useful predictors of suicidal behavior.

Psychiatric comorbidity may also lower the threshold for suicidal behavior. Studies suggest that in depressed patients, the presence of alcohol abuse, substance abuse, PTSD, or CBPD can increase the propensity to act on suicidal thoughts. Environmental influences that lower the threshold for suicidal

behavior include marital isolation, early childhood parental loss, and a childhood history of physical or sexual abuse. An individual's threshold for suicide is also lowered by feelings of low self-esteem. Several factors appear to raise the threshold for suicidal behavior. These protective factors include religious affiliation, moral constraints, concerns about social disapproval, coping and survival skills, and family responsibility. These attitudes may act as an incentive not to commit suicide.

This article describes a comprehensive model for categorizing risk factors for suicidal behavior into those that act as stressors and those that lower the threshold for acting on suicidal ideas. This model may guide research into methods of prevention and treatment of suicidal behavior and, ultimately, save lives.

Stress as a Precipitant of Suicide

The Adequacy of Stressors

The Situation

Survivors

Assisted Suicide

Preventing Suicide

Glossary

Assisted suicide Suicidal acts in which the individual is assisted. This may take the form of a prescription being written for a lethal dose of a medication or of someone else administering the lethal dose/injection.

Attempted suicide A suicide act that the individual survives. At the lower end of medical lethality, attempted suicide may be difficult to distinguish from self-mutilation. In Europe, the trend has been to call suicidal acts that are not life-threatening parasuicide or deliberate self-harm.

Completed suicide

A suicidal act that results in the death of the individual. It is sometimes called fatal suicide.

The study of suicide is complicated by difficulties in determining intentionality, or whether the suicidal person has engaged in intentional self-harm. Recently, suicide nomenclature has evolved such that clinicians, researchers, and others can now use a common language to understand the suicide-related behavior. Beyond assisted suicide, attempted suicide, and completed suicide, suicidal ideation, defined as any self-reported thoughts of engaging in suicide-related behavior, is also commonly used. In addition, parasuicide is used rather than attempted suicide to describe self-destructive behavior in the absence of clear intent of suicide. The term suicidality should be avoided because it refers to a broad range of suicide-related behaviors.

The 2001 National Strategy for Suicide Prevention noted that 650 000 people receive emergency care for suicide attempts and 30 000 die by suicide each year in the United States. Given the loss of life and impact on families and communities, suicide has been declared a serious public health problem. The goals of the National Strategy are to (1) promote awareness of suicide as a public health problem; (2) develop broad-based support for suicide prevention; (3) develop and implement strategies to reduce the stigma associated with mental illness, substance abuse, and suicide; (4) develop and implement community-based suicide prevention programs; (5) promote efforts to reduce access to lethal methods of self-harm; (6) implement

effective training to assess at-risk individuals and provide effective intervention; (7) develop clinical and professional practices; (8) increase access to mental health services; (9) improve the reporting and media portrayal of suicide-related behavior; (10) promote research on suicide and suicide prevention; and (11) improve and expand surveillance systems. The overarching objective is a comprehensive and integrated approach to reducing the loss associated with suicide and related behaviors. Many other nations have also developed national strategies for reducing the incidence of suicide.

The 2002 Institute of Medicine (IOM) report for the United States is an excellent and comprehensive resource for understanding suicide's history; impact; manifestations across gender, ethnic, age, and other demographic groups; and protective factors or suicide buffers. For example, although African Americans were previously thought to be protected from suicide, studies show that in the 1980s and 1990s Black men ages 25–34 years demonstrated suicide rates comparable to that of White men in the same age group. The most recent data and trends are cited in the IOM report, including the cost to society due to medical expenses for emergency intervention and treatment, lost productivity, and reduced wages. The value of lost productivity alone was estimated to be \$11.8 billion in 1998.

Suicide can be studied at the societal or at the individual level. Sociological research has focused primarily on the societal rate of completed suicide, a rate that is relatively stable over time. At the individual level, in contrast, both completed and attempted suicides have been studied and both behaviors are difficult to predict. Suicide is rare, with the completed suicide rate, for example, seldom rising above 40 per 100 000 per year in any nation. The rarity of suicidal behavior means that prediction instruments (typically based on personal data and psychiatric and psychological measures) will have a high rate of false positives (people predicted to be suicides who, in fact, will not kill themselves). Differences between the predictability of suicide at societal and individual levels has an analogy in radioactive decay, in which the half-life of a mass of, say, uranium is easily determined and constant, whereas predicting which particular uranium atom will decay next is impossible.

Suicide fits well with the diathesis–stress model of psychiatric disorder, in which only those individuals with a predisposition (diathesis) to develop a disorder do so when faced with particular stressors. It should be noted, however, that both factors can influence one another – a diathesis can make it more likely that a person will encounter stressors and a stressor

can strengthen a diathesis. For example, a stress such as the loss of a loved one can be more stressful for a person who has few friends than for someone without that diathesis. Likewise, a tendency to have few friends may be increased by the experience of interpersonal losses.

Diathesis

Many predisposing factors for suicide have been identified by research.

1. Neurophysiological dysfunction, especially problems in serotonergic pathways, may underlie the psychiatric disorders for which the risk of suicide is high.
2. The majority of suicides are found to have been suffering from a psychiatric disorder. In particular, suicide is common in those suffering from affective disorders such as a major depressive disorder or a bipolar affective disorder (manic–depression), substance abuse (both drug and alcohol abuse), and schizophrenia.
3. Childhood experiences such as the loss of a parent (or other primary caregiver) through death, especially if the death is from suicide, or divorce and physical or sexual abuse are commonly found in the personal histories of suicides. Lester studied 30 suicides famous enough to have a biography written about them (such as Ernest Hemingway) and found that exactly half had experienced the loss of a parent or other loved one. Fourteen of the 15 suicides who had experienced such a loss had experienced this loss between the ages of 6 and 16. However, it is not clear whether such experiences increase the risk of suicide directly or whether they increase the risk of psychiatric disorders, which in turn increases the risk of suicide. For example, a history of physical and sexual abuse is associated with a wide spectrum of later psychiatric disorders, including depression, anxiety, eating disorders, and substance abuse, in addition to suicidal behavior.
4. The mood of potential suicides is characterized by depression. Suicidal individuals obtain high scores on self-report measures of depression, and the level of depression of those attempting suicide increases with the seriousness of their suicidal intent. Depression includes many components: physical symptoms (such as sleep and appetite problems), mood symptoms (such as depression and guilt), and cognitive symptoms (such as hopelessness). Suicidal individuals tend to be hopeless, believing that things will not improve and will probably worsen in the future. Aaron Beck has

found that self-report measures of hopelessness are stronger predictors of suicidal intent than self-report measures of depression. Edwin Shneidman has called the psychological pain experienced by potential suicides psychache.

5. Suicidal individuals appear to think differently from nonsuicidal individuals. Research has found that suicidal individuals have a reduced ability to generate alternatives other than death for the problems they are facing; they tend to think in dichotomous categories, polarizing their evaluations into extremes, such as good versus bad or right versus wrong; and they tend to think rigidly.
6. In addition, the risk of suicide is strongly associated with simple demographic characteristics. Suicide rates in the United States are higher in men than in women, in the elderly than in the young, in Whites than in African Americans, and in the divorced and widowed than in the single and married. These demographic correlates of suicide risk vary from country to country, however.

In 2005, Joiner developed a comprehensive interpersonal-psychological theory of attempted and completed suicide and hypothesized that suicidal people must (1) be capable of lethal self-injury, (2) perceive that they are a burden to loved ones, and (3) believe that they are not connected to a valued group or relationship. These three necessary precursors answer the question of why people do or do not die by suicide. For example, few people die by suicide, relatively speaking, and interpersonal-psychological theory suggests that the acquired ability to inflict self-harm requires courage, fearlessness, and habituation to self-harm. Joiner asserted that individuals must also see themselves as ineffective and burdensome to loved ones. In contrast, a sense of belonging to a valued group acts as a suicide buffer. In sum, the confluence of three factors must be in place. However, those who engage in repeated attempts at suicide are at high risk for suicide.

Joiner's theory explains several research findings. For example, the relatively low rate of suicide despite the high lifetime prevalence of lifetime suicide thoughts is explained by the absence of two or more factors (such as the incapability of self-injury and a sense of connectedness). Thus, not everyone who considers suicide or feels hopeless will attempt suicide. Note that those who die by suicide use more lethal means and therefore demonstrate a stronger propensity to self-harm. Although women are less likely to die by suicide than men, those women who die are as likely as men to use very lethal methods (e.g., a gun and hanging). The role of neurophysiological factors in suicide is related to the impact of

neurotransmitters on negative emotionality, which may, in turn, incite feelings of burdensomeness and contributes to a lesser feeling of belongingness.

Stress as a Precipitant of Suicide

Suicides are found to have experienced higher levels of stressful events in the past year than nonsuicidal individuals. Not only is the level of stressful events higher, but typically there is a further increase in this already high level in the weeks immediately prior to the suicide. These conclusions are based on retrospective studies of the lives of completed suicides in the hours, days, weeks, and months prior to their death – a procedure called a psychological autopsy. In a psychological autopsy, mental health professionals, usually guided by an interview schedule, seek out and interview friends, colleagues, and relatives of the suicide and inquire into the suicide's recent behaviors and psychological state.

Commentators have suggested that men become suicidal more as a reaction to performance failure, whereas women become suicidal more as a reaction to romantic conflict. However, research has indicated few differences between the stressors encountered by female and male suicides. Large differences in precipitating stressors by age have been observed. Stressors experienced by adolescent and young adult suicides tend more often to involve negative interpersonal events, such as friction and break-ups with loved ones and problems involving work, finances, and the criminal justice system. In contrast, stressors of elderly suicides tend more often to involve medical problems and intrapsychic states such as depression. These differences by age are found both in psychological autopsy studies and in content analyses of suicide notes.

Similar differences have been observed in attempted suicides and those thinking about the possibility of killing themselves, who also are found to have experienced more recent stressful events than nonsuicidal psychiatric patients or general medical patients. Two studies from the 1990s illustrate the role of stress. Paul Dean and colleagues found that suicidal ideation in college students was positively associated with self-ratings of negative life events in the past year and, in addition, depression, hopelessness, and perfectionism, and was negatively associated with scores on a reasons-for-living scale. John Reich and colleagues found that suicidal ideation in a sample of elderly adults (mean age 70 years) was associated with worsening health in the prior 6 months and, in addition, self-reported feelings of helplessness, fatalism, confused thinking, and low self-esteem.

The Adequacy of Stressors

Older adults who commit suicide are typically seen as having experienced more adequate stressors than younger adults and adolescents who kill themselves. Elderly suicides are frequently suffering from medical problems, often severe, and have experienced a succession of losses (of loved ones and friends, of employment and work, and of physical abilities). Thus, the precipitants of their suicides appear to involve severe stress. Most of the examples of rational suicide involve such cases, and indeed assisted-suicide laws passed in the United States and other nations are usually restricted to those who are terminally ill. In contrast, the precipitants of suicide in adolescents and young adults are sometimes seen as inadequate causes of suicide. Such suicides are, therefore, viewed as impulsive and not rational and are less predictable.

The Situation

The situation in which potential suicides find themselves may also play a role in precipitating their suicides. The easy availability of lethal methods for suicide may play a role. Research on the effects of restricting easy access to methods for suicide (such as detoxifying domestic gas, placing emission controls on cars, and restricting the number of pills prescribed for psychiatric disorders) has shown that this can be an important tactic for preventing suicide.

The publicity given to suicides, especially suicides by celebrities, has been shown to lead to an increase in the suicide rate in the following few days, especially among those of the same age and sex as the celebrity. Suicide among peers can have a contagion effect, precipitating suicidal behavior in those with those characteristics that predispose the individual to suicide. Suicides occurring in schools have aroused particular concern, and there are now guidelines for staff in responding to the suicide of a student.

Survivors

The experience of having a loved one complete suicide can be extremely traumatic for those left behind. In addition to the normal grieving process, there is additional stress from feelings of guilt and responsibility (could something have been done to help the suicide and prevent their death?), anger (over their suicide), and stigma from others who may view the survivors with suspicion or simply not know how to respond.

In addition, some suicides kill themselves in such a way that their loved ones discover the body. The discovery of the body of a loved one drowned,

hanging from a hook, with cut wrists, or, even worse, grossly disfigured by a bullet is extremely traumatic. It creates a final picture of the loved one that is difficult to exorcize.

Survivors have become very active in their communities and in professional organizations devoted to suicide prevention. They have formed self-help groups, sometimes with the involvement of clinicians, to meet and assist one another in dealing with the complicated grief that accompanies the suicide of a loved one. Books have been written for survivors and the membership of the American Association of Suicidology has a large contingent of survivors.

Assisted Suicide

The reluctance of people to kill themselves with violent methods and the desire of suicidal individuals to have others assist them in their suicides have led to widespread debate about assisted suicide. Derek Humphry published the book *Final Exit*, which details the medications and dosages for suicide – a do-it-yourself book that became a best seller in the United States. Similar books in other nations (such as France) have been banned.

In physician-assisted suicide, typically the goal is to have physicians provide a sufficient amount of a lethal medication for the client to complete suicide. In most regions that have legalized this process (e.g., in Oregon and the Netherlands), this process is restricted to those who are terminally ill, and there is a detailed procedure for those applying for physician-assisted suicide that must be followed.

However, on occasion, physicians and relatives have assisted the suicidal individual in the actual killing, for example, by administering the lethal injections or by shooting the person. This is illegal in almost all nations and jurisdictions, and those assisting in the actual killing can be, and indeed sometimes are, charged with murder. Nevertheless, such incidents have occurred and continue to occur. The line between assisting someone to commit suicide and murdering someone is, therefore, blurred in these cases, and society is vigorously debating these issues at the present time.

Preventing Suicide

The prevention of suicide uses several strategies. Many communities now have suicide prevention centers that maintain telephone counseling services staffed primarily by well-trained lay people who can provide crisis counseling for those who are suicidal. The American Association of Suicidology has a directory of such centers in the United States and also

inspects and certifies the centers if asked to do so. Befrienders International, Life Line, and the International Federation of Telephone Emergency Services are three international organizations that have established and coordinated crisis counseling and suicide prevention services in other nations.

Educational programs have been established to inform students in school about suicide, especially about recognizing signs of suicidal intent in their peers, and to provide them with resources to which they can refer their suicidal peers. Educational programs have also occasionally been established for general practitioners and family physicians so that they can diagnose depression in their patients more accurately and prescribe antidepressants more effectively.

Clinicians have been developing counseling techniques especially designed for suicidal clients to supplement the general systems of psychotherapy (such as transactional analysis and reality therapy) that guide therapists. These new techniques have been primarily in the field of cognitive therapy and are based on the results of research on the cognitive processes of suicidal individuals discussed earlier.

The 2002 report from the IOM examined prevention and medical and psychosocial intervention, but also looked at barriers to research, treatment, and effective prevention. For example, suicide is more likely to occur within 1 month after discharge from psychiatric institutions than at other times. The report noted that a significant gap in clinical trials is the absence of high-risk patients. Because effective treatments (psychopharmacological and psychosocial) involve long-term maintenance in which the individual is required to have contact with a health-care professional, adequate health-care insurance coverage is essential. School-based programs that target high-risk school-age children are essential for suicide prevention among youth and seem to result in increased social support, self-efficacy, and self-esteem among youth at risk for suicide, but research on these intervention programs is

complicated by poor control groups and limited long-term follow up.

Durkheim's Theory

Henry and Short's Theory

Naroll's Theory

Culture Conflict

Measuring Regional Stress

Multivariate Studies of Regional Suicide Rates

Nonfatal Suicide Behavior

Glossary

*Attempted
suicide*

A suicide act that the individual survives. Attempted suicide is at the lower end of medical lethality and may be difficult to distinguish from self-mutilation. In Europe, the trend has been to call suicidal acts that are not life-threatening parasuicide or deliberate self-harm.

*Completed
suicide*

A suicidal act that results in the death of the individual. It is sometimes called fatal suicide.

Sociological research into suicide has focused primarily on the rate of completed suicide in regions (nations or regions within nations), a rate that is relatively stable over time. Ecological studies examine suicide rates of a set of regions at one point in time, usually to see which social characteristics of the regions predict the suicide rates. Time-series studies examine suicide rates of one region each year for a period of time, usually to see which social characteristics predict the yearly suicide rate. Time-series cross-sectional studies examine suicide rates of a number of different countries simultaneously for a period of time. Here multivariate ecological studies of suicide are reviewed. Three major theories of suicide are presented: Emile Durkheim's, Andrew Henry and James Short's, and Raoul Naroll's. The role of culture conflict in increasing the rate of suicide is illustrated. Finally, the possibility of sociological studies of nonfatal suicide is discussed.

Durkheim's Theory

The first major theory of the social suicide rate was proposed in 1897 by Emile Durkheim. Durkheim argued that two broad social characteristics are responsible for determining the social suicide rate: social integration and social regulation. Social integration is the extent to which the members of the society are bound together in social networks. Very high levels of social integration lead to high rates of altruistic suicide, whereas very low levels lead to high rates of egoistic suicide. Social regulation is the extent to which the desires and behavior of the members of the society are restricted by social norms and customs. Very high levels of social regulation lead to high rates of fatalistic suicide, whereas very low levels lead to high rates of anomic suicide.

There has been a great deal of research purporting to test this theory, for example, exploring the association between divorce rates and suicide. Divorce is presumed to weaken the extent of social integration and reflect weak social regulation, and therefore higher divorce rates should be positively associated with higher suicide rates. Both ecological studies and time-series studies have confirmed this predicted positive association between divorce rates and suicide rates.

However, research rarely examines the roles of both social integration and social regulation separately, partly because it is difficult to operationalize the two social characteristics independently of one another. The few studies that have attempted to do so have found that measures of social integration are stronger correlates of suicide rates than measures of social regulation.

Furthermore, no research has attempted to classify suicides in the societies under study into Durkheim's four types. Durkheim proposed, for example, that low levels of social integration result in high levels of egoistic suicide. Therefore, a proper test of Durkheim's theory requires the dependent variable to be the rate of egoistic suicide. The rate of egoistic suicide is not identical to the total social suicide rate, which is, instead, the combined rate of all four of Durkheim's types of suicides.

Henry and Short's Theory

Henry and Short proposed a theory based on both psychoanalytic theory and the frustration-aggression hypothesis. They assumed that the primary target of aggression for a frustrated individual is another person. What inhibits this other-oriented aggression and results in the aggression being directed inward onto the self?

Henry and Short proposed that the primary factor was the strength of external restraints on behavior. When behavior is required to conform rigidly to the demands and expectations of others, the role of others in the responsibility for the self's frustration and misery is strong. As a consequence, other-oriented aggression is legitimized. When external restraints are weak, the self must bear the responsibility for the frustration and misery. Thus, other-oriented aggression is not legitimized, and self-directed aggression becomes more likely.

These proposals lead to interesting predictions, many of which have been confirmed. The oppressed in a society have clear external sources to blame for their misery – their oppressors. Therefore, other-oriented aggression is legitimized for them, and they will tend to have higher rates of assault and, in the extreme, homicide. In contrast, the oppressors in the society have fewer external sources to blame for their misery because, as the dominant group, they have tremendous opportunities for advancement and gratification. Therefore, the oppressors in the society will tend to have higher rates of depression and, in the extreme, suicide. These predicted differences in the suicide and homicide rates are found for African Americans and Whites in the United States.

Henry and Short's theory can also explain the positive association between the quality of life and suicide rates. When the quality of life in a nation is high, there are few external sources to blame for one's misery, and so suicide will tend to be more common. This association has been confirmed in ecological studies both of nations and of U.S. states.

Naroll's Theory

Raoul Naroll, an anthropologist, proposed a theory of social suicide rates that has relevance to stress. Naroll proposed that suicide was more likely in those who were socially disoriented, that is, in those who lack or lose basic social ties (such as those who are single or divorced). Because not all socially disoriented people commit suicide, there must be a psychological factor that makes suicide a more likely choice when a person is socially disoriented, and Naroll suggested that it was the person's reaction to thwarting disorientation contexts. Such contexts involve a weakening of the person's social ties as a result of the actions of other people or him- or herself (but not as a result of impersonal, natural, or cultural events). Being divorced by a spouse or murdering one's spouse are examples of such contexts, but storm damage to property or losing a spouse to cancer are not. In thwarting disorientation contexts, some people commit protest suicide, which Naroll defined as

voluntary suicide committed in such a way as to come to public notice (and, therefore, excludes unconsciously motivated suicides and culturally motivated suicides such as *suttee*).

Durkheim's theory of suicide refers more to steady-state characteristics of the society as major explanatory variables, whereas Naroll's theory suggests the role of sudden, acute changes in a society – societal stressors. Furthermore, Naroll's theory is phrased in a way that makes it more usefully applied to individuals as well as to societies as a whole.

Culture Conflict

Cultures often come into conflict, a source of stress that may increase the suicide rate. For example, the conflict between traditional Native American culture and the dominant Anglo-American culture has often been viewed as playing a major role in precipitating Native American suicide. Philip May reviewed three hypotheses that might have relevance here. In the social disorganization hypothesis, the dominance of the Anglo-American culture is viewed as forcing Native American culture to change and as eroding traditional cultural systems and values. This changes the level of social regulation and social integration, important causal factors for suicide in Durkheim's theory of suicide.

A second hypothesis focuses on cultural conflict. The pressure from the educational system and mass media on Native Americans, especially on youth, to acculturate, a pressure that is opposed by their elders, leads to great stress for the youth. A third hypothesis focuses on the breakdown of the family in Native American tribes. Parents are often unemployed, substance abusers, and in trouble with the law, and divorce and desertion of the family by one or both parents are common. The suicide rates of three groups of Native Americans in New Mexico, the Apache, Pueblo, and Navajo (whose suicide rates were 43.3, 27.8, and 12.0 per 100 000 per year, respectively), were in line with their levels of acculturation as rated by May (high, moderate, and low, respectively).

Measuring Regional Stress

Linsky and co-workers measured the stress level of each of the U.S. states in three areas. For economic stress, they used business failures, unemployment claims, strikes, bankruptcies, and mortgage foreclosures. For family stress, they used divorces, abortions, illegitimate births, and fetal and infant deaths. For community stress, they used disasters, new housing starts, new welfare recipients, high school dropouts, and interstate migration. They found that states with

higher levels of stress also had higher suicide rates. Interestingly, however, the ratings of the stress level of each state based on responses from a national survey, which asked residents about their perceived level of stress, were not associated with the state suicide rates.

Multivariate Studies of Regional Suicide Rates

The accuracy of official national and regional rates of suicide has been questioned by Jack Douglas and others, who have argued that these rates are biased by the values of the local coroners and medical examiners and of the resident populations. However, despite the fact that regions do have different standards

for classifying a death as suicide, Peter Sainsbury and Brian Barraclough showed that the suicide rates of immigrants to one country from different nations are in almost the same rank order as the suicide rates of nations of origin.

The suicide rates of 71 nations reporting to the World Health Organization are shown in Table 1 for males and females. An inspection of the table reveals two basic findings: (1) in all countries, males have higher suicide rates than females, which suggests that differential gender socialization (e.g., males are socialized to be more aggressive and to keep their feelings inside) significantly impacts suicide rates; and (2) suicide rates vary significantly among the 71 countries, which suggests that cultures differ in the degree to which suicide is viewed as an acceptable behavior.

Table 1 Suicide rates around the world^a

<i>Country</i>	<i>Year reported</i>	<i>Males</i>	<i>Females</i>	<i>Country</i>	<i>Year reported</i>	<i>Males</i>	<i>Females</i>

Cutright and Fernquist term this phenomenon the culture of suicide.

Simpson and Conklin identified two clusters of variables that were associated with national suicide rates: (1) a cluster that had the highest loading from the percentage of Muslims in the population and (2) a cluster that seemed to assess economic development. Suicide rates were lower in nations with less economic development and where Islam was a more important religion. Two other clusters (Christianity and the Eastern bloc) were not associated with suicide rates.

In similar study of the social correlates of national suicide rates, Lester identified 13 orthogonal (independent) factors for social variables, only one of which was associated with suicide rates, a factor that seemed to measure economic development (with high loadings from such social variables as low population growth and high gross domestic product per capita). Thus, these two studies agreed in finding that economic development is associated with higher suicide rates. Cutright and Fernquist reported that classical Durkheimian variables measuring social integration (i.e., divorce, fertility, and religiosity), as well as female labor-force participation, were strong predictors of cross-national suicide rates for both males and females of different age groups.

For the United States, a similarly designed study conducted by Lester identified a cluster of variables that seemed to measure social disintegration (high divorce and interstate migration rates, low church attendance, and high per capita alcohol consumption), and this was the strongest correlate of the suicide rates of the states.

Nonfatal Suicide Behavior

Almost all sociological research and theories have hitherto been proposed for fatal (completed) suicide. Nonfatal suicidal behavior has been relatively ignored. It is important that better epidemiological studies of attempted suicide and suicidal ideation be conducted so that sociologists can develop theories of these behaviors. The World Health Organization has sponsored a comparative epidemiological study of attempted suicide in 15 sites. Unfortunately, the sites are limited to cities in European nations and do not encompass these nations as a whole. However, the study is innovative and may lay the groundwork for more comprehensive epidemiological studies in the future. Linsky and colleagues have obtained estimates of the incidence in the previous year of suicidal ideation in U.S. states and sought social correlates of this.

Thus, such research is possible, and it is to be hoped that more studies are planned along these lines.

Stressful Characteristics of the Surgical Situation
Responses of Surgical Patients at Emotional, Cognitive, and
Physiological Levels
Surgical Stress and Postoperative Recovery
Psychological Preparation for Surgery

Glossary

<i>Psychological preparation for surgery</i>	Psychological methods aimed at reducing preoperative anxiety and aiding the recovery process.
<i>Surgical outcomes</i>	Variables reflecting the quality of postoperative recovery, for example, postoperative pain, pain medication length of stay, clinical recovery measures (e.g., wound healing), physiological indices (heart rate, blood pressure, palmar sweat gland activity, and cortisol level), negative affect, and satisfaction.
<i>Surgery</i>	A subset of invasive medical procedures involving some form of anesthesia.

The introduction into the health-care system and hospitalization can be a stressful experience on their own. Among the aspects of hospitalization considered to be most stressful, the following were identified in a sample of elderly medical inpatients: communication problems with health-care professionals; diagnostic and therapeutic procedures; the hospital environment (noise, rigid routines, etc.); worries about the home situation and the separation from home; insufficient information about diagnosis and prognosis; and fear of dependency, loss of autonomy and control. In addition to uncertainties about their illnesses (because of unclear communication) and the unfamiliar surroundings of a hospital ward, therefore, patients encounter additional stress because they must undergo medical procedures and examinations. Even some outpatient procedures such as dental treatments or blood donation can be stressful. Normally patients report increases in anxiety in anticipation of procedures such as surgery, endoscopy, cardiac catheterization, cancer screening, and chemotherapy. In addition to the anticipatory anxiety

associated with the procedure itself, diagnostic procedures such as cancer screening are characterized by a prolonged period of anxiety between screening and receiving the result.

Of all medical procedures, surgery is perhaps the most threatening event because it contains many unpredictable and uncontrollable features such as losing consciousness due to the administration of a general anesthetic, the anticipation of postoperative pain, and the surgical trauma related to the incision. This article concentrates on surgical procedures and describes the stressful characteristics associated with being hospitalized for surgery. We review the literature on the psychological and physiological responses to the experience of surgery and summarize findings from studies investigating psychological preparation for surgery.

Stressful Characteristics of the Surgical Situation

There are obvious potential threats for the surgical patient: anesthesia, pain, physical restriction, life-threatening procedures, and being away from home. Evidence suggests that the lack of predictability and control are significant contributors to the stressful experience of surgical patients. It is usually the case that we need to be able to predict an event in order to be able to control it. But the reverse does not follow – being able to predict an event does not necessarily mean we can control it. Such is the case for elective surgery, which accounts for the vast majority of surgical interventions.

This evidence confirms that there are common characteristics of the surgical situation that are identified by most patients as stressful. However, it seems likely that different types of surgical procedures produce different types of stress. A useful way of distinguishing between the various procedures is by considering the function of the procedure (diagnostic, treatment, or both) and the time line and nature of stress associated with the procedure. A further distinction can be drawn between procedural stress (i.e., the stress associated with the negative aspects of the actual procedure itself) and outcome stress (i.e., longer-term fears and concerns related to the results of the treatment or procedure). To illustrate the latter point, some operations may have more positive characteristics in terms of their expected outcome than others, for example, restoration (hip replacement) versus the removal of physical function (leg amputation).

Responses of Surgical Patients at Emotional, Cognitive, and Physiological Levels

Emotional Responses

Most studies investigating emotional responses to surgery have shown elevated levels of anxiety both before and after surgery. In some groups of patients, postoperative anxiety levels may be even higher than those measured preoperatively. Previous results indicating that anxiety is high before but not after surgery have been dismissed as being methodically flawed. Although anxiety has been, for obvious reasons, the most frequently assessed emotional response, it has been shown that surgical patients may also experience high levels of nervousness, depression, anger, and boredom.

In summary, the literature suggests that emotional responses to the surgical situation may vary as a function of the type of operation and, therefore, outcome concerns. Study results also point to the possibility of effective interventions not only before but also after surgery.

Cognitive Responses

Several studies have shown that patients' main worries are more related to the outcome of the operation than to the operation itself. Patients also worry significantly about normal everyday matters such as family and home, perhaps exacerbated by hospitalization and the impending surgery. As in the treatment of depression, the cognitive elements of surgical patients' stress response may be critical in indicating the most promising intervention approach to alleviate distress.

Physiological Responses

The most thorough research on physiological responses to surgery has been carried out on indices of sympathetic-adrenomedullary activity, both because they are readily measurable in surgical patients and because this highly responsive physiological axis has been widely used in well-controlled laboratory studies of psychological stress. The most consistent finding is that of a reduction in palmar sweat gland activity prior to surgery followed by recovery to normal levels postoperatively. This pattern follows closely the pattern of subjective distress and pain, indicating that sweat gland activity is reduced by the stress of surgery. Some authors, however, have argued that the palmar sweating pattern of surgical patients is related to the effort rather than to the distress aspect

of stress, that is, that changes in palmar sweating are due to changes in activity levels.

A more recent line of research has investigated neuroendocrine and immune changes in response to surgery and wound healing. Postoperative elevations in plasma levels of adrenaline, cortisol, and β -endorphins reflect sympathetic nervous system and hypothalamic-pituitary-adrenal axis activation. Evidence for immune suppression during surgery comes from studies showing the suppression of natural killer cell activity, proliferation of lymphocyte responses to mitogens, and changes in lymphocyte populations.

In order to interpret physiological responses to surgery as psychophysiological phenomena, it is necessary to disentangle the effects that are due to the experience of stress from those that are caused by the surgical trauma and other medical interventions (e.g., anesthesia). Apart from anesthesia and surgery itself, physiological changes may be caused by alterations in diet and ambulation and by medications, especially starvation before surgery and premedication or sedation on the night prior to surgery. Although these problems have at least been partly addressed in studies of the sympathetic-adrenomedullary axis, studies of other pathways are still at a very early stage and cannot support any firm conclusions.

Surgical Stress and Postoperative Recovery

Despite a strong effect of physical factors such as extent of tissue damage caused by the surgical trauma on postoperative recovery, there is variability across patients who have undergone the same procedure. It is unclear what accounts for this variability, and this has led to the suggestion that psychological factors such as anxiety and depression may play some part in determining the duration or quality of postoperative recovery.

There is considerable theoretical and empirical support for the relevance of psychosocial factors to postoperative recovery. These include demographic variables, such as age, gender, and socioeconomic status, and also personality variables, such as anxiety, neuroticism, coping style and social support. Most of the available literature today suggests a linear association between preoperative anxiety and success of recovery, in that the more anxious the patient is before the operation, the less favorable the postoperative recovery. There is even evidence that preoperative anxiety is related to intraoperative adjustment.

There is increasing evidence from psychoneuroimmunological work that stress and pain have a negative effect on endocrine and immune functions and

may thereby lead to delays in wound healing and other clinical complications. Although wound healing is only one postoperative outcome among a whole range, it is certainly a central parameter for short-term outcome in recovery from surgery. Kiecolt-Glaser et al. offer a biobehavioral model suggesting a number of routes through which psychological and behavioral responses can influence surgery and postoperative recovery.

Psychological Preparation for Surgery

There is now substantial agreement that psychological preparation for surgery is beneficial for patients. It is important, however, to establish which benefits can be achieved by psychological preparation and if all forms of preparation are equally effective. Results from a number of meta-analyses suggest that significant benefits can be obtained on all the major outcome variables (i.e., negative affect, pain, pain medication, length of stay, behavioral and clinical

indices of recovery, physiological indices, and satisfaction). The methods of psychological preparation employed include the provision of information about sensations and procedures, behavioral instructions, cognitive interventions, relaxation, and hypnosis. Procedural information and behavioral instructions show the most ubiquitous effects, both being clearly effective in improving all postoperative outcomes.

History of the Concept of Survivor Guilt
Moral Features of Survivor Guilt
Sense and Purpose of Survivor Guilt
Range of Manifestations of Survivor Guilt
Treatment of Survivor Guilt

Glossary

<i>Guilt</i>	An internal emotional judgment (an aspect of conscience) of having been bad or having done wrong to another.
<i>Survivor</i>	A person who has lived through a trauma.
<i>Trauma</i>	An experience in which a person's life has been grossly threatened and out of which a variety of biological, psychological and social wounds and scars results.

History of the Concept of Survivor Guilt

Survivor guilt as a clinical entity was emphasized for the first time in Holocaust literature in the 1960s. Psychiatrists such as Krystal and Niedeland were struck with the ubiquity of feelings of intense, unabating guilt for having survived among their Holocaust survivor patients. Survivor guilt came to be quickly recognized in other traumatic situations, including the Hiroshima atom bomb, combat, disasters, and civilian bereavement. It was noted after 9/11; indeed, it can occur in all traumatic situations, whether natural or man made.

A special form of survivor guilt may be said to occur in rescuers and helpers who blame themselves for not having saved those for whom they viewed themselves as responsible. More subtle forms can occur in clinicians who feel guilt for their own well-being in the face of their patients' suffering.

Moral Features of Survivor Guilt

The most striking feature of survivor guilt is its moral judgment of self-blame. It is directed to the survivor's

undeserved survival in contrast to others' deaths. An individual suffering from survivor guilt often states that the dead should be alive instead of him- or herself. This feeling may be enhanced when the individual was saved by another who died.

A common subtype of survivor guilt relates to not having saved others. The implication is that the survivor could have and should have saved others, but due to selfishness did not, instead saving him- or herself, thereby causing suffering and death to others. This feeling is enhanced if the person's usual role, such as spouse, parent, or rescuer, was to protect those who died, or if the person did indeed put his or her survival ahead of others.

However, a striking feature of survivor guilt is the contrast between the torment of self-blame of survivors and their innocence by any objective criteria. For instance, Holocaust survivors often blamed themselves for not following or saving their loved ones who were murdered, when actually they were separated at gunpoint and through physical force. Children who survived by hiding blamed themselves for the deaths of their parents. The Holocaust taught the paradox that victims are prone to survivor guilt while perpetrators rationalize theirs.

Unjustified survivor guilt occurs in all traumatic situations. Medical staff may blame themselves for not saving unsavable patients. A child may grow up with unwarranted guilt for separation from parents or parental death.

Sense and Purpose of Survivor Guilt

Observations of acute phases of traumatic situations indicate that survivor guilt is an unpleasant, instinctive social cue (that may be reinforced by others' anger and blame) that can be appeased only through helping others. For instance, in a disaster those whose houses survive often appease their very intense guilt by sheltering those whose houses are destroyed. Survivor guilt thus helps to preserve as many people (or genes) in the community as possible.

Later survivor guilt may be less useful practically, though it may prime adaptive reparative action for subsequent traumatic situations. It may also preserve the survivor's retrospective hope that 'if only's may yet be able to be executed. Further, Danieli suggests that the guilt is a buffer against moral chaos and existential helplessness, as it preserves some assumption of moral order in the universe. Last, the guilt perpetuates close emotional links to the dead.

Range of Manifestations of Survivor Guilt

If survivor guilt is appeased by effective rescue of others, it may be seen as a temporary stress. If it

fails and become part of a trauma, it is lived and relived as part of the wounds and scars of the trauma. Then the following biological, psychological, and social manifestations may occur singly or in a variety of combinations.

Physiological Responses

Thus far, the physiological accompaniments of survivor guilt have not been delineated.

Psychological Responses

Emotion Survivor guilt is one of the most painful human emotions. It may be felt as both mental anguish and a physical heart-wrenching pain in the chest directed toward the dead, but turned angrily back on the survivor him- or herself.

Cognitions Poignant traumatic events may return in feelings, thoughts, images, dreams, and flashbacks, along with ruminations about what the survivor should have done but did not do. Cognitive schemas and meanings develop, such as that the survivor is an irresponsible person, even a destroyer of life.

Defenses Intense pain of survivor guilt such as having caused the death of beloved peoples, may be central in survivor defense formations. Psychic numbing, dissociation, and repression may fragment coherent awareness. Identification may lead to physical symptoms similar to the ones the dead had suffered. Displacement may lead to blaming others. Sublimation may lead to devotion to saving others. Some survivors may take on rescuer or helper professions.

Social Responses

In acute situations, people may vacillate between appeasing survivor guilt by helping others and other essential survival options. After the acute phase of the trauma, people may wring their hands as they anguish about the choices they made. They may blame themselves and withdraw in order to avoid the imagined blame of the question "Why did you survive?" Survivors may play down their survivorship, and may especially avoid enjoyment and vitality, as they can exacerbate their feelings of guilt. Sublimatory activity may be channeled through choosing helping or rescuing work and professions.

Specific social settings may lead to characteristic responses. For instance, bereaved parents often withdraw to extremes, and emotional numbing admixed with intense blame and self-blame often result in divorce.

Associated Clinical Features

Survivor guilt may be associated with other judgments, such as shame and injustice. The sense of

injustice may come from having been unfair to others, but also from having been put in unfair situations.

Survivor guilt may interfere with grieving and is often at the kernel of unresolved grief and depression. Hence it may need to be resolved before the grieving process can proceed.

Treatment of Survivor Guilt

Prevention of survivor guilt is part of the rationale for strict, following of protocols, early disaster intervention, debriefing, and grief therapy. Its resolution is a common goal in later psychotherapies.

The first principle of treatment of survivor guilt is its recognition. Next, thorough investigation of the facts of the circumstances reveals how survivor guilt is objectively untenable. Its evolutionary sense and hence its presence is explained, and alternative, hopeful cognitive views are explored. With the thawing defenses of the survivor, the emotional pain of survivor guilt is identified, processed, and assimilated in the context of an empathic, therapeutic relationship. The survivor's sense of morality is retrieved with the realization that past circumstances, not the survivor,

were irrational and bad. Seeing him- or herself as a victim, not as a perpetrator, allows the survivor to grieve losses and to achieve new hopeful meanings for him- or herself. The survivor can then reclaim a purposeful life.

Sympathetic Nervous System

D S Goldstein

National Institute of Neurological Disorders and Stroke,
Bethesda, MD, USA

Published by Elsevier Inc.

Epinephrine

The main hormone of the adrenomedullary hormonal system.

Norepinephrine

The sympathetic neurotransmitter.

Historical and Conceptual Overview

Role of the Sympathetic Nervous System in Homeostasis
Norepinephrine: The Sympathetic Neurotransmitter

Glossary

<i>Sympathetic nervous system</i>	A major component of the autonomic nervous system. The main sympathetic neurotransmitter for cardiovascular regulation is norepinephrine. The main sympathetic neurotransmitter for sweating is acetylcholine.
<i>Adrenomedullary hormonal system</i>	The hormonal component of the autonomic nervous system.
<i>Norepinephrine</i>	The main sympathetic neurotransmitter for cardiovascular regulation.

Historical and Conceptual Overview

The term sympathetic nervous system originates in the second-century teaching of Galen that the peripheral nerves, conduits for distributing the animal spirit in the body, enable concerted, coordinated (i.e., sympathetic) functioning of body organs. The notion of the sympathetic nervous system, therefore, antedated by approximately 14 centuries Harvey's demonstration of the circulation of the blood.

The sympathetic nervous system is a major component of the autonomic nervous system. In the late nineteenth century, Langley introduced the phrase autonomic nervous system to refer to nerves emanating from cell bodies in ganglia alongside the spinal column and in the gastrointestinal-tract walls. Langley defined three components: sympathetic, with preganglionic

cells in the thoracolumbar spinal cord; parasympathetic (a word he coined), with preganglionic cells in the brain stem or sacral spinal cord; and enteric, with preganglionic cells near or in the target organs. The nerves of these systems were thought to differ from those of the somatic nervous system, not only in terms of anatomy but also in terms of function. Somatic nerves mediate conscious, observable changes in skeletal muscle contraction and therefore movement, whereas autonomic nerves mediate unconscious, largely unobservable changes in smooth muscle contraction independently (autonomously) of the central nervous system.

The early-twentieth century American physiologist Walter B. Cannon introduced the word homeostasis. Cannon added a hormonal component to the autonomic nervous system when he theorized that the sympathetic nervous system and the adrenal gland worked together as a unit to maintain homeostasis in emergencies. In the 1930s, he even formally proposed that the sympathetic nervous system used the same chemical messenger – adrenaline – as did the adrenal gland (in 1946, von Euler correctly identified the sympathetic neurotransmitter in mammals as norepinephrine). Accumulating evidence supports the independent regulation of the sympathetic nervous and adrenomedullary hormonal systems, refuting the concept of a unitary sympathoadrenal system. Nevertheless, Cannon's views about the unitary function of the neural and hormonal components of the sympathoadrenal system prevail in stress research.

Sweating, whether to control body temperature (thermoregulatory), evoked by eating spicy food (gustatory), or accompanying fear or anxiety (emotional), is mediated by the sympathetic cholinergic system, in which acetylcholine rather than norepinephrine is the chemical messenger. The autonomic nervous system, therefore, can be viewed as having five components: sympathetic noradrenergic, sympathetic cholinergic, parasympathetic cholinergic, adrenomedullary, and enteric.

Role of the Sympathetic Nervous System in Homeostasis

Adjustments in sympathetic nervous activity accompany virtually every human action and reaction and constitute the main means for the acute regulation of cardiovascular function. According to Goldstein's 1995 theory, comparator homeostats use the sympathetic nervous system as an effector for different stress responses. The sympathetic nervous and adrenomedullary hormonal effectors interact in complex ways with many others, including the hypothalamic–pituitary–adrenocortical system, the endogenous

opiate system, vasopressin, the parasympathetic nervous system, and the renin–angiotensin–aldosterone system, in determining responses to stressors.

The sympathetic nervous system consists of nerve networks. Because the axons come from cells in ganglia rather than directly from the spinal cord or brain stem, sympathetic nerves supplying body organs are mainly postganglionic; however, most sympathetic nerves supplying adrenomedullary chromaffin cells are preganglionic, releasing acetylcholine and thereby stimulating membrane nicotinic receptors.

Stresses associated with sympathetic nervous system activation typically include a component of active movement. Patterned sympathetic nervous system activation during stress produces adaptive shifts in the distribution of blood volume or in glandular secretion ([Figure 1a](#)). When these changes suffice to maintain homeostasis, the organism does not experience them consciously, but when the brain senses that these responses are not or will not mitigate the effects of the stressor, the situation reaches consciousness and adrenomedullary hormonal system activation ensues ([Figure 1b](#)). Examples of situations associated with prominent increases in sympathoneural outflows include orthostasis, exercise, the postprandial state, cold exposure, and the performance of nondistressing locomotor tasks.

In response to perceived global metabolic threats from external or internal stimuli, increased neural outflow to the adrenal medulla elicits catecholamine secretion into the adrenal venous drainage. In humans, the predominant catecholamine in the adrenal venous drainage is epinephrine (synonymous with adrenaline). Epinephrine rapidly reaches all cells of the body, with the exception of most of the brain, producing a wide variety of hormonal effects at low blood concentrations. We can comprehend the many effects of epinephrine in terms of the body's countering of acute threats to survival that mammals have perennially faced, such as sudden lack of metabolic fuels, trauma with hemorrhage, intravascular volume depletion and hypotension, and fight-or-flight confrontations. Distress accompanies all these situations, the experience undoubtedly fostering the long-term survival of the individual and the species by motivating avoidance learning, enhancing the registration of the event in long-term memory, and producing signs universally understood among other members of the species.

Stresses eliciting adrenomedullary hormonal system activation typically also elicit hypothalamic–pituitary–adrenocortical activation, as indicated by high circulating levels of corticotropin or glucocorticoids; increases in release of endogenous opioids, as indicated by high plasma levels of β -endorphin; and

Figure 1 Overview of effects of the activation of (a) the sympathetic nervous system, where norepinephrine acts as the main neurotransmitter, and (b) the adrenomedullary hormonal system, where epinephrine acts as the main hormone. Because the sympathetic nervous system is a neural network, sympathetic nerves to different regions can be activated differentially during stress, producing redistributions of blood flow to body organs. Norepinephrine released from sympathetic nerves generally contracts smooth muscle cells, eliciting glandular secretion, vasoconstriction, and myocardial contraction. Renal vasoconstriction produces an anti-natriuretic effect. Cutaneous vasoconstriction produces pallor. The net effect of systemic vasoconstriction is to increase the total peripheral resistance to blood flow in the body. This, combined with myocardial stimulation, increases blood pressure. In humans, the main hormone released by the adrenal medulla is epinephrine (adrenaline). Epinephrine affects the function of most organs and produces generalized effects such as increased metabolic rate, increased blood glucose levels, hypokalemia, increased lactate production, increased alertness, increased platelet aggregability, and intensification of emotions. Aggreg., aggregation; BP, blood pressure; Cut., cutaneous; Dec., decrease; Inc., increase; RAS, renin–angiotensin–aldosterone system.

vasopressin secretion even when sympathetic nervous system activity declines.

Norepinephrine: The Sympathetic Neurotransmitter

The chemical transmitter at most cardiovascular sympathetic nerve endings is norepinephrine. The binding

of norepinephrine to adrenoceptors on cardiovascular smooth muscle cells contracts the cells. The body's myriad arterioles largely determine total resistance to blood flow and therefore contribute in an important way to blood pressure. Sympathetic nerves enmesh blood vessels in latticelike networks in the adventitial outer surface that extend inward to the adventitial-medial border, with the concentration of sympathetic

nerves increasing as arterial caliber decreases, so that small arteries and arterioles, the smallest nutrient vessels possessing smooth muscle cells, possess the most intense innervation. The unique architectural association between sympathetic nerves and the vessels that determine peripheral resistance has enticed cardiovascular researchers, particularly in the area of autonomic regulation, for many years. Sympathetic vascular innervation varies widely among vascular beds, with dense innervation of resistance vessels in the gut, kidney, skeletal muscle, and skin. Sympathetic stimulation in these beds produces profound vasoconstriction, whereas stimulation in the coronary, cerebral, and bronchial beds elicits weaker constrictor responses, consistent teleologically with the goal of preserving blood flow to vital organs during

stress. Cardiac sympathetic stimulation increases the force and rate of the heartbeat and also augments intracardiac electrical conduction and automaticity.

Norepinephrine released from sympathetic nerve terminals acts mainly locally. Only a small proportion of released norepinephrine reaches the bloodstream. The indirect and distant relationship between plasma norepinephrine levels and sympathetic nerve activity can complicate interpreting plasma norepinephrine levels in response to stressors, pathophysiological situations, and drugs.

Norepinephrine Synthesis

The enzymatic steps in norepinephrine synthesis have been characterized in more detail than those for any other neurotransmitter (Figure 2). Catecholamine

Figure 2 Overview of steps in norepinephrine synthesis, release, reuptake, and metabolism. Hydroxylation of the amino acid tyrosine is the enzymatic rate-limiting step in catecholamine biosynthesis. Tyrosine hydroxylase catalyzes the conversion of tyrosine to DOPA. L-aromatic-amino acid decarboxylase (LAAAD) catalyzes the conversion of DOPA to dopamine. Dopamine-β-hydroxylase is localized to large dense-core vesicles in noradrenergic cells. After uptake of axoplasmic dopamine into the vesicle, dopamine-β-hydroxylase catalyzes the conversion of dopamine to norepinephrine. According to the exocytosis theory, increased transmembrane entry of ionized calcium fosters fusion of the vesicles with the axonal membrane. Endogenously released norepinephrine is taken back up into sympathetic nerve terminals by Uptake-1 and taken up into nonneuronal cells by Uptake-2. Norepinephrine in the axoplasm can be translocated back into the vesicles or converted to dihydroxyphenylglycol by monoamine oxidase (MAO) in the outer mitochondrial membrane. Norepinephrine in nonneuronal cells is converted to normetanephrine by catechol-O-methyltransferase. Dihydroxyphenylglycol can diffuse into the bloodstream or can be taken up by nonneuronal cells and converted to methoxyhydroxyphenylglycol, which is a major end product of norepinephrine metabolism. Dopamine in the axoplasm can be translocated into vesicles and converted to norepinephrine or can be converted to dihydroxyphenylacetic acid by MAO. Dihydroxyphenylacetic acid can diffuse into the bloodstream or can be converted extraneuronally to homovanillic acid, the main end product of dopamine metabolism. The processes of catecholamine uptake and metabolism are generally independent of actions by adrenoceptors on the nerve terminals or nonneuronal cells. COMT, catechol-O-methyltransferase; DA, dopamine; DHPG, dihydroxyphenylglycol; DOPA, 3,4-dihydroxyphenylalanine; DOPAC, dihydroxyphenylacetic acid; HVA, homovanillic acid; LAAAD, L-aromatic-amino acid decarboxylase; MAO, monoamine oxidase; MHPG, methoxyhydroxyphenylglycol; NE, norepinephrine; NMN, normetanephrine; TH, tyrosine hydroxylase; TYR, tyrosine.

biosynthesis begins with the uptake of the amino acid tyrosine into the cytoplasm of sympathetic neurons and adrenomedullary cells. Tyrosine hydroxylase catalyzes the conversion of tyrosine to 3,4-dihydroxyphenylalanine (DOPA). This is the enzymatic rate-limiting step in catecholamine synthesis. The enzyme is almost saturated under normal conditions, so alterations in dietary tyrosine intake normally do not affect the rate of catecholamine biosynthesis under baseline conditions. Tetrahydrobiopterin, ionic iron, and molecular oxygen are required for tyrosine hydroxylase activity. Exposure to stressors that increase sympathoadrenal outflows augments the synthesis and concentration of tyrosine hydroxylase by multiple and complex mechanisms. Short-term mechanisms include feedback inhibition and phosphorylation of the enzyme, the latter depending on membrane depolarization, contractile elements, and receptors. Long-term mechanisms include changes in tyrosine hydroxylase synthesis, probably determined by transsynaptic induction and retrograde transport.

L-aromatic-amino-acid decarboxylase (LAAAD, also called DOPA decarboxylase) in the neuronal cytoplasm catalyzes the rapid conversion of DOPA to dopamine. Many types of tissues contain this enzyme. The activity of the enzyme depends on pyridoxal phosphate, which is vitamin B-6. Although LAAAD metabolizes most of the DOPA formed in catecholamine-synthesizing tissues, some endogenously produced DOPA enters the circulation. This provides the basis for using plasma DOPA levels to examine catecholamine synthesis. By inhibiting the conversion of DOPA to dopamine in the periphery, LAAAD inhibitors such as carbidopa enhance the efficacy of L-DOPA treatment of Parkinson's disease.

Dopamine- β -hydroxylase catalyzes the conversion of dopamine to norepinephrine in tissues that synthesize catecholamines. The enzyme is confined to the vesicles in catecholamine-producing cells. Dopamine- β -hydroxylase contains, and its activity depends on, copper. Because of this dependence, children with Menkes disease, a rare, inherited X-linked recessive disorder of copper metabolism, have neurochemical evidence of decreased conversion of dopamine to norepinephrine and compensatorily increased tyrosine hydroxylation. Dopamine- β -hydroxylase activity also requires ascorbic acid (vitamin C), which provides electrons for the hydroxylation.

Norepinephrine Storage

Vesicles in sympathetic nerves actively remove and trap axoplasmic amines. The vesicular monoamine transporter resembles the neuronal membrane monoamine transporters structurally, but it is relatively nonspecific

for catecholamines and serotonin. Magnesium and ATP accelerate vesicular uptake, and reserpine effectively and irreversibly blocks it. Vesicles generated near the Golgi apparatus of the cell bodies travel by axonal transport in the axons to the nerve terminals. Noradrenergic vesicles may also form by endocytosis within the axons. Varicosities in sympathetic nerves contain two types of cytoplasmic vesicles: small dense-core (diameter 40–60 nm) and large dense-core (diameter 80–120 nm). Cores of both types of vesicle contain abundant ATP, the norepinephrine : ATP ratio averaging approximately 1 : 4. The vesicles also contain at least three types of polypeptides: chromogranin A, enkephalins, and neuropeptide Y. The extracellular fluid levels of each of these compounds have been considered as putative indices of exocytosis.

Norepinephrine Release

According to the exocytotic theory, acetylcholine depolarizes the terminal membranes by increasing membrane permeability to sodium ion. The increased intracellular sodium levels directly or indirectly enhance the transmembrane influx of calcium ion via voltage-gated channels. The increased cytoplasmic calcium concentration evokes a cascade of as yet incompletely defined biomechanical events, resulting in the fusion of the vesicular and axoplasmic membranes. The interior of the vesicle exchanges briefly with the extracellular compartment, and the soluble contents of the vesicles diffuse into the extracellular space. As predicted from this model, manipulations other than the application of acetylcholine that depolarize the cell, such as electrical stimulation or increased potassium ion concentrations in the extracellular fluid, also activate the voltage-gated calcium channels and trigger exocytosis.

During sympathetic neuronal or adrenomedullary chromaffin cell activation, the simultaneous stoichiometric release of soluble vesicular contents – ATP, enkephalins, chromogranins, and dopamine- β -hydroxylase – without a similar release of cytoplasmic macromolecules has provided biochemical support for the exocytosis theory of noradrenergic neurotransmission. Electron micrographs occasionally have shown an omega sign, with an apparent gap in the cell membrane at the site of fusion of vesicle with the axoplasmic membrane. Ultrastructural evidence has suggested the release of the contents of large as well as small dense-core vesicles by exocytosis.

Sympathetic nerve endings can also release norepinephrine by calcium-independent, nonexocytotic mechanisms. One such mechanism probably is reverse transport through the neuronal uptake carrier. The indirectly acting sympathomimetic amine, tyramine,

releases norepinephrine nonexocytotically because tyramine releases norepinephrine independently of calcium and does not release dopamine- β -hydroxylase. As predicted from the ionic requirements for neuronal reuptake, increases in intracellular sodium concentrations, such as produced by ouabain, enhance carrier-mediated efflux of norepinephrine. Myocardial ischemic hypoxia evokes the calcium-independent release of norepinephrine. The hydrophilic nature of catecholamines and their ionization at physiological pH probably prevent norepinephrine efflux by simple diffusion.

Pharmacological stimulation of receptors on noradrenergic terminals affects the amount of norepinephrine released during cellular activation. Substantial evidence supports inhibitory presynaptic modulation by norepinephrine itself via α_2 -adrenoceptors on sympathetic nerves. This modulatory action appears to vary with the vascular bed under study, being prominent in skeletal muscle beds such as the forearm, relatively weak in the kidneys, and virtually absent in the adrenals. In addition to local feedback control of norepinephrine release, reflexive long-distance feedback pathways via arterial and cardiac baroreceptors elicit reflexive changes in sympatho-neural impulse activity. Alterations in receptor numbers or of intracellular biomechanical events after receptor activation also affect responses to agonists. These factors therefore regulate norepinephrine release by trans-synaptic local and reflexive long-distance mechanisms.

Norepinephrine Disposition

Unlike acetylcholine, which is inactivated mainly by extracellular enzymes, norepinephrine is inactivated mainly by uptake into cells (Figure 2), with subsequent intracellular metabolism or storage. Reuptake into nerve terminals (Uptake-1) is the predominant means of terminating the actions of released norepinephrine. Dopamine is a better substrate than norepinephrine is for uptake via the cell-membrane norepinephrine transporter.

Neuronal uptake absolutely requires intracellular potassium ion and extracellular sodium ion and functions most efficiently when chloride ion accompanies the sodium. Uptake-1 requires energy and is carrier mediated. Transport does not directly require ATP; however, maintaining ionic gradients across cell membranes depends on ATP, and the carrier uses the energy expended in maintaining the transmembrane sodium gradient to cotransport amines with sodium. Many drugs or *in vitro* conditions inhibit Uptake-1, including cocaine and tricyclic antidepressants.

Norepinephrine taken up into the axoplasm by the Uptake-1 transporter is subject to two fates: translocation into storage vesicles and deamination by monoamine oxidase (MAO). The combination of enzymatic breakdown and vesicular uptake constitute an intraneuronal sink, keeping the cytoplasmic concentrations of norepinephrine very low. Reserpine effectively blocks the vesicular transport of amines from the axoplasm into the vesicles. This not only shuts down the conversion of dopamine to norepinephrine but also prevents the conservative recycling of norepinephrine. Reserpine, therefore, rapidly depletes norepinephrine stores.

Neural and nonneural tissues contain MAO, which catalyzes the oxidative deamination of dopamine to form dihydroxyphenylacetic acid and norepinephrine to form dihydroxyphenylglycol. Because of the efficient uptake and reuptake of catecholamines into the axoplasm of catecholaminergic neurons and because of the rapid exchange of amines between the vesicles and axoplasm, the neuronal pool of MAO, located in the outer mitochondrial membrane, figures prominently in the overall functioning of catecholaminergic systems. The isozyme MAO-A predominates in neural tissue, whereas both MAO-A and MAO-B exist in nonneural tissue. MAO inhibitors are effective antidepressants. A phenomenon known as the cheese effect limits their clinical use. In patients taking MAO inhibitors, the administration of sympathomimetic amines such as those found in many nonprescription decongestants or the ingestion of foods such as aged cheese, wine, and meat, which contain tyramine, can produce paroxysmal hypertension. Tyramine and other sympathomimetic amines increase the loss of norepinephrine from sympathetic vesicles, and the blockade of MAO augments the bioavailability of ingested tyramine. When given alone, MAO inhibitors usually decrease blood pressure and can produce orthostatic hypotension by unknown mechanisms.

Nonneuronal cells remove norepinephrine actively by a process called Uptake-2, characterized by the ability to transport isoproterenol; susceptibility to blockade by O-methylated catecholamines, corticosteroids, and β -haloalkylamines; and an absence of susceptibility to blockade by Uptake-1 blockers. In contrast with Uptake-1, Uptake-2 functions independently of extracellular sodium. The Uptake-2 carrier has little if any stereoselectivity and has low affinity and specificity for catecholamines. For instance, extraneuronal cells remove imidazolines such as clonidine by Uptake-2. Whereas reverse transport via the Uptake-1 carrier requires special experimental conditions, reverse transport via the Uptake-2 carrier is

readily demonstrated. Thus, during the infusion of a catecholamine at a high rate, the catecholamine can accumulate in extraneuronal cells, with reentry of the catecholamine into the extracellular fluid via the Uptake-2 carrier after the infusion ends.

Catechol-O-methyltransferase in nonneuronal cells and adrenomedullary chromaffin cells catalyzes the O-methylation of dihydroxyphenylglycol to form methoxyhydroxyphenylglycol and of dihydroxyphenylacetic acid to form homovanillic acid. Plasma levels of dihydroxyphenylglycol and dihydroxyphenylacetic acid probably mainly reflect neuronal metabolism of norepinephrine and dopamine. Catechol-O-methyltransferase also catalyzes the conversion of norepinephrine to normetanephrine and epinephrine to metanephrine. Uptake-2 and catechol-O-methyltransferase probably act in series to remove and degrade circulating catecholamines. The methyl group donor for the reaction is S-adenosyl methionine. Immunohistochemical studies have indicated extraneuronal localization of catechol-O-methyltransferase in most tissues, such as the liver and kidney. Because of the extraneuronal localization of catechol-O-methyltransferase, recently introduced assay methods for metanephrines have enabled refined assessments of extraneuronal metabolism of catecholamines.

Most of the metabolism of catecholamines takes place within the same cells where the amines are synthesized. This mainly occurs secondary to leakage of catecholamines from vesicular stores into the cytoplasm. The stores exist in a highly dynamic equilibrium, with passive outward leakage counterbalanced by inward active transport controlled by vesicular monoamine transporters.

In catecholaminergic neurons, the presence of MAO-A leads to the formation of reactive catecholaldehydes. The contribution of these toxic aldehydes to neurodegenerative processes depends on the dynamics of vesicular-axoplasmic monoamine exchange and enzyme-catalyzed conversion to inert deaminated acids or alcohols. In sympathetic nerves, the aldehyde produced from norepinephrine is converted to dihydroxyphenylglycol, not dihydroxymandelic acid, as textbooks often indicate. Subsequent extraneuronal O-methylation consequently leads to the production of methoxyhydroxyphenylglycol, not vanillylmandelic acid. Vanillylmandelic acid is instead formed in the liver by the oxidation of methoxyhydroxyphenylglycol catalyzed by alcohol dehydrogenase.

Compared to intraneuronal deamination, extraneuronal O-methylation of norepinephrine and epinephrine to metanephrines represent minor pathways of metabolism. The single largest source of metanephrines is the adrenal medulla. Vanillylmandelic acid and methoxyhydroxyphenylglycol, the products of the combined O-methylation and deamination of norepinephrine, are the two main end products of norepinephrine metabolism, vanillylmandelic acid (as just noted) formed mainly in the liver. Adrenomedullary chromaffin cells express catechol-O-methyltransferase, as do pheochromocytomas, which are clinically important chromaffin cell tumors. Pheochromocytoma cells produce large amounts of metanephrines from catecholamines leaking from stores. These metabolites are thus particularly useful for detecting these tumors. The large contribution of intraneuronal deamination to catecholamine turnover, and the dependence of this on the vesicular axoplasmic monoamine exchange process, help explain how synthesis, release, metabolism, turnover, and stores of catecholamines are regulated in a coordinated fashion.

Actions of Synthetic Glucocorticoids

Clinical Aspects

Glossary

*Blood–brain
barrier*

Dynamic barrier of endothelial cells between blood and brain, protecting the brain from potentially neurotoxic compounds and maintaining a constant internal environment in the brain.

*Corticotropin
releasing hor-
mone (CRH)*

A 41 amino acid residue peptide that is synthesized in hypothalamic nerve cells and mediates the neural control of ACTH release.

Glucocorticoids

Steroid hormones that affect carbohydrate and protein metabolism, regulate the activity of the hypothalamic-pituitary-adrenal (HPA) axis, and have anti-inflammatory and immunosuppressive effects. Endogenously, they are synthesized in the adrenal cortex, released on stimulation by adrenocorticotrophic hormone (ACTH).

Mineralocorticoids

Steroid hormones that affect water and electrolyte balance. Naturally occurring glucocorticoids often have also substantial mineralocorticoid action.

Introduction

Synthetic glucocorticoids are widely used in basic, preclinical, and clinical research. The importance of these compounds in stress research is based on their

suppressive effects on the activity of the hypothalamic-pituitary-adrenal axis (HPA axis). Their main clinical applications, however, are based on their effective anti-inflammatory and immunosuppressive actions. The first synthetic glucocorticoids were developed in the late 1950s as drugs for treating rheumatoid arthritis. In basic research the compounds are mainly used to unravel the properties of the glucocorticoid receptor (GR).

All synthetic glucocorticoids are structurally related to hydrocortisone (cortisol) and corticosterone, which are the main endogenous glucocorticoids of primates and rodents, respectively. However, synthetic glucocorticoids often bind to the GR with a higher affinity and thus have much more potent glucocorticoid actions on the HPA axis, the immune system, and energy metabolism than the naturally occurring hormones. Their mineralocorticoid actions on salt retention/sodium homeostasis, although reduced, are still a disadvantage, especially for long-term treatment. The synthetic glucocorticoid RU28362 lacks this mineralocorticoid activity and is a pure glucocorticoid.

The group of glucocorticoids includes many compounds (see [Table 1](#) for some examples). The most commonly used synthetic glucocorticoids are prednisone/prednisolone and dexamethasone.

Chemical Aspects

The structure of all glucocorticoids is basically the same. Most of them are 21-carbon polycyclic compounds with a steroid structure, a fused 17-carbon atom ring system with an aliphatic side chain at carbon-17, a keto group at carbon-3, one or two double bonds in the A-ring, and an oxygen at carbon-11 ([Figure 1](#)). Different side groups determine the differences in glucocorticoid and mineralocorticoid properties. Reducing the salt-retaining properties was the main effort in the early development of new glucocorticoids. For example, the fluorination of dexamethasone (9 α -fluoro-11 β ,17 α ,21-trihydroxy-16 α -methylpregna-1,4-diene-3,20-dione) highly increases its anti-inflammatory potency, but unfortunately also its salt-retaining properties. The inserted 16 α -methyl group, however, markedly reduces the mineralocorticoid properties, negating the effect of the 9 α -fluoro

Table 1 Characteristics of several common glucocorticoids

Compound	Relative affinity of glucocorticoid receptors (GRs)	Relative potency		Half-life (h)		Comments
		Glucocorticoid	Mineralocorticoid	Plasma	Biological	
Hydrocortisone (cortisol)	1	1	1	1.5	8–12	Endogenous glucocorticoid of humans Drug of choice for replacement
Cortisone	0.01	0.8	0.8	0.5	8–12	Inactive until converted to hydrocortisone
Corticosterone	0.85	0.3–0.5	5–15		8–12	Endogenous glucocorticoid of rodents Not used in humans
Dexamethasone	7.1	25–30	0.5	3–4	36–72	Drug of choice for suppression of ACTH production
Prednisolone	2.2	3.5–4	(0.6–0.8)	2–3	12–36	Inactive until converted to prednisolone
Prednisone	0.05	4	(0.6–0.8)	3–3.5	12–36	
Methylprednisolone	11.9	5	0.5	3	12–36	Pure GR agonist; not used in humans
RU28362	9		0			
Betamethasone	5.4	25–30	0.5	6.6	36–54	GR antagonist
Triamcinolone	1.9	5	0.1	1.5	12–36	
Mifepristone (RU486)	7	–	–	20–30		

atom. Prednisolone (11 β ,17 α ,21-trihydroxypregna-1,4-diene-3,20-dione) is a dehydrogenated derivative of cortisol with an enhanced glucocorticoid and declined mineralocorticoid activity. The most selective ligand RU28362 (11 β ,17 β -dihydroxy-6-methyl-17 α (1-propynyl)-androsta-1,4,6-triene-3-one) has only been used in experimental research up to now. More recently developed selective GR ligands have a non-steroidal structure.

Pharmacokinetics

Glucocorticoids are small, highly lipophilic molecules and therefore are not very soluble in water, but are easily soluble in ethanol, polyethylene glycol (PEG), or dimethyl sulfoxide (DMSO).

Because of their strong lipophilicity, the orally administered glucocorticoids are readily absorbed. Prednisone and cortisone are biologically inactive and are quickly converted to the active compounds prednisolone and cortisol/hydrocortisone, respectively, by dehydrogenation at the carbon-11 hydroxyl group in the liver. In the blood, synthetic glucocorticoids are mainly bound to albumin, a common plasma protein with low affinity. Unlike the endogenous glucocorticoids, most synthetic glucocorticoids are not bound to corticosteroid-binding globulin (CBG). This plasma protein with a high affinity for naturally

occurring corticosteroids, but low presence in plasma, binds prednisolone but not dexamethasone. Plasma half-life is enlarged in the presence of a double bond (prednisolone) or a fluorine atom (dexamethasone) because of decreased rate of metabolism. The plasma half-lives are between 2 and 4 h (Table 1). Because of the modifying action on gene transcription, the duration of the biological effects is much longer than the plasma half-life. It is not the presence of the drug itself but the long-lasting interaction of the ligand receptor complex and the protein synthesis system that accounts for the biological actions. The biological half-life can be up to 72 h (Table 1).

Synthetic glucocorticoids are metabolized in the same way as the endogenous corticosteroids. The main metabolizing tissue is the liver, where steroids are conjugated with glucuronic acid or sulfuric acid. The unchanged parent drug and its metabolites are secreted in the urine, for over 60% (in the case of dexamethasone) and up to 90% (in the case of prednisolone) of the administered dose within 24 h. Changes in plasma half-life of glucocorticoids may result from changed hepatic metabolism due to liver or renal malfunction.

The passage of synthetic glucocorticoids through the blood–brain barrier is hampered because of the presence of multidrug resistance 1a (mdr1a) P-glycoprotein. Recently it was shown that this drug efflux

Figure 1 Chemical structures of some common glucocorticoids. Cortisol and corticosterone are endogenous corticosteroids. Cortisol and hydrocortisone have the same chemical structure; the former refers to the naturally occurring glucocorticoid, while the latter refers to the synthetic variant. Cortisone is an inactive endogenous derivative of cortisol. Prednisolone, prednisone, dexamethasone, and RU28362 are synthetic glucocorticoids. Mifepristone is a glucocorticoid antagonist.

pump, which is expressed at the apical membranes of endothelial cells of the blood–brain barrier, hampers the access of moderate amounts of dexamethasone and prednisolone to the brain. Ablation of the gene in the *mdr1a* knockout (–/–) mice resulted in enhanced uptake of dexamethasone and prednisolone.

The most effective receptor antagonist of glucocorticoids is mifepristone (RU486) [17 β -hydroxy-11 β -(4-dimethylaminophenyl)-17 α -(1-propynyl)-estra-4,9-dien-3-one]. This compound, originally developed as a progesterone antagonist, expresses a high affinity for the GR, but binding generally does not result in stimulation of transcription. RU486 antagonizes glucocorticoid effects *in vitro* and inhibits the effect of

dexamethasone on HPA activity *in vivo*. RU486 has weak agonistic properties in some *in vitro* settings, depending on the molecular mechanism of action, and possibly in *in vivo* settings in the absence of glucocorticoid agonists.

Actions of Synthetic Glucocorticoids

The main glucocorticoid actions are mediated by GRs, nuclear receptors present in the cytosol of almost every cell in the body. The corticosteroids bind with high affinity to the GR and in some degree to mineralocorticoid receptors (MRs). MRs are less abundantly present in the body. Most of the synthetic

glucocorticoids have relatively low residual mineralocorticoid potencies (Table 1).

In absence of P-glycoprotein, glucocorticoids easily cross the cell membrane, entering the cell by passive diffusion. Upon binding, the activated steroid receptor complex is translocated from the cytoplasm to the nucleus. The next step is binding to DNA or to transcription factors. Binding to DNA involves binding to glucocorticoid responsive elements (GREs) and subsequent recruitment of coactivator proteins, resulting in activation (or inhibition) of the transcription of target genes (referred to as transactivation). Following binding to transcription factors, the steroid receptor complex effects the transcription of non-GRE containing genes (referred to as transrepression). Transrepression is believed to be the main mechanism of the anti-inflammatory/immunosuppressive actions of glucocorticoids, while transactivation is believed to be responsible for the numerous side effects. This concept has fueled the extensive search for GR ligands with reduced metabolic and HPA suppressant actions while retaining their immunosuppressive/anti-inflammatory actions. The first compounds with dissociated glucocorticoid activities at the molecular level did not show the desired dissociation of beneficial and undesirable actions *in vivo*. A new interesting approach is emerging in the literature that focuses on the development of improved glucocorticoids based on the concept of differential cofactor recruitment by the GR depending on the ligand involved. These new ligands are useful in the understanding of basic GR functioning.

Regarding stress, the main action of glucocorticoids is their suppression of stress-induced HPA axis activity via GRs. GRs are found in all HPA axis structures, hypothalamus, hippocampus, and pituitary. Synthetic glucocorticoids reduce basal plasma levels of ACTH and corticosterone/cortisol during the circadian rise, and they suppress stress-induced rises in ACTH and corticosteroid plasma levels. In spite of the high affinity for synthetic glucocorticoids displayed by GRs *in vitro*, synthetic glucocorticoids (e.g., dexamethasone) do not accumulate in the hippocampus, because of the presence of mdrla P-glycoprotein efflux transporter at the blood-brain barrier. It is therefore likely that the pituitary gland is the primary site of action for the suppressant effects on stress-induced ACTH and corticosterone secretion, particularly at low doses of synthetic glucocorticoids.

Clinical Aspects

Synthetic glucocorticoids are therapeutically used mainly as effective and wide-acting anti-inflammatory

and immunosuppressive drugs. They affect all types of inflammatory reactions independently of the initiating stimulus. They suppress the body's defense reactions, preventing overreaction of the defense mechanisms, which may become damaging if not controlled. Unfortunately, the wide range of actions of glucocorticoids also results in many, sometimes life-threatening side effects on bone, glucose, and HPA axis. More selective nonsteroidal glucocorticoid ligands are currently in development.

Another clinical application is substitution therapy in the case of adrenal insufficiency (Addison's disease), although cortisol and cortisone are more commonly used in that case. Dexamethasone is also used to reduce brain edema. For diagnostic purposes the dexamethasone suppression test (DST, sometimes combined with a CRH challenge) is widely used to test the hypothalamic-pituitary-adrenocortical function. A low dose results in suppression of the hydrocortisone secretion. Failure of suppression implies hypersecretion of corticotropin or of glucocorticoids due to Cushing's syndrome. In psychiatry the DST is used to test patients with major depressive disorders. A large proportion of depressed patients displays enhanced HPA activity. They show impaired suppressibility of cortisol and thus escape from dexamethasone suppression.

Mifepristone (RU486) was recently demonstrated to rapidly relieve psychotic depressed patients from psychotic symptoms. After a brief 7-day treatment with high doses of this antagonist, patients showed a dramatic improvement.

Management of Stress in Systemic Lupus Erythematosus

Glossary

<i>Antinuclear antibodies</i>	Proteins in the blood that react with the nuclei of cells; seen in 96% of patients with SLE, most with other autoimmune diseases, and in 5% of healthy individuals, they are the hallmark of autoimmune disease.
<i>Apoptosis</i>	Programmed cell death; in SLE, the mechanism is altered such that cells that should die do not. Fragments from these cells lead to autoimmune reactions.
<i>B cells</i>	White blood cells that make autoantibodies.
<i>Immune complexes</i>	The complex of an antigen and antibody; in SLE, they are not cleared properly and damage tissue, producing an inflammatory response.
<i>T cells</i>	White blood cells responsible for immunological memory; in SLE, T suppressor cells fail to suppress immune responses.

Lupus erythematosus is an autoimmune disorder that afflicts 1 million people in the United States; 90% of patients are female, and 90% develop it during their reproductive years. Epidemiological surveys suggest that African Americans, certain Asian groupings

(e.g., Chinese), Native Americans, and Hispanics are more susceptible to the disorder. Lupus is classified into many groupings: chronic cutaneous (discoid) lupus (15%), systemic lupus (75%), drug-induced lupus (5%), and lupus overlapping with rheumatoid arthritis, scleroderma, or inflammatory myositis (also called cross-over syndromes, mixed connective tissue disease) (5%).

Etiopathogenesis

A critical dose of 30 thus far identified susceptibility genes causes enough immune response abnormalities to sustain the production of pathogenic autoantibodies and immune complexes. The genes are turned on by infections, increased exposure to ultraviolet light or other environmental toxins, at least 70 known prescription drugs, exposure to increased estrogen or other sex hormones, and severe stress. Antigens are formed that are immunogenic, lead to high quantities of apoptotic cells, produce molecular mimicry (especially microbes), and/or undergo epitope spreading. There are intrinsic abnormalities of B and T lymphocytes. These cells are activated by lower concentrations of antigens than normal, have sustained surface expression of activation markers, and are relatively resistant to apoptosis, which allows them to escape regulation. There is a consequent release of cytokines and chemokines by these cells, which results in inflammation. In this milieu, autoantibody subsets become pathogenic and idiotypic networks promote more antibody production. Immune complexes (consisting of antigen and antibody) are formed that favor capture rather than elimination, and tissue is further damaged. The role that stress plays in this process is discussed here.

Clinical Presentation

Approximately one-half of all systemic lupus erythematosus (SLE) cases are non-organ threatening.

In other words, the heart, lung, kidney, liver, central nervous system, and hematopoietic system (with regards to hemolytic anemia and autoimmune thrombocytopenia) are spared. Patients usually complain of constitutional symptoms of fatigue, fevers, swollen glands, or weight loss along with arthralgias, myalgias, and pleuropericardial (serositis) discomfort. These individuals are usually diagnosed after 1–3 years of symptoms. Organ-threatening disease is a serious subset of lupus and is associated with the need for immune-suppressive approaches. Manifestations include myocarditis, endocarditis, pulmonary hypertension or hemorrhage, mesenteric vasculitis, interstitial lung disease, autoimmune hepatitis, thrombotic thrombocytopenic purpura, retinitis, vestibulitis with hearing loss, proteinuria, seizures, psychosis, and edema. The presentation is usually quite dramatic and diagnostic delays are uncommon. The 1997 American College of Rheumatology (ACR) revised criteria for SLE are listed in [Table 1](#).

Laboratory testing, along with appropriate electrical studies and imaging, is very useful in diagnosing and following the disorder. Initial testing includes a complete blood count, comprehensive metabolic profile, muscle enzymes, urinalysis, chest x-ray, and electrocardiogram. Serologic parameters encompass an antinuclear antibody (ANA) with a reflex panel for a variety of autoantibodies, obtaining certain protein and acute-phase reactant determinants (which screen for inflammation) such as anti-DNA, anti-Smith antibodies (anti-Sm), Sjögren's syndrome antigens (anti-SSA and anti-SSB), complement components, sedimentation rate, C reactive protein, and a serum protein electrophoretic screening. Occasionally, additional determinations such as two-dimensional echocardiography, brain imaging, lumbar puncture, or electromyograms can be useful. One-third of lupus patients have a procoagulant set of autoantibodies

known as antiphospholipid antibodies that can predispose patients to a thromboembolic event.

Management

Non-organ-threatening disease is managed by employing physical measures such as avoidance of the sun, pacing activities to minimize fatigue, moist heat for painful joints, a general conditioning program, work-station modifications to enhance job performance, and a low fat, well-balanced diet. Stress reduction is also critical. Individuals respond best to a combination of sunscreens applied to sun-exposed areas, topical corticosteroids, and nonsteroidal anti-inflammatories. Antimalarials (e.g., hydroxychloroquine) have anti-inflammatory disease-modifying properties and can decrease the risk of dissemination. Low doses of corticosteroids may be used until antimalarials are effective several months later, and immune-suppressive regimens are rarely indicated.

Patients with organ-threatening disease are usually managed with a combination of corticosteroids (moderate to high dose, usually starting at 1 mg/kg/day prednisone or its equivalent). Steroid-sparing agents such as methotrexate and leflunomide can be employed for milder cases, but serious presentations respond best to azathioprine, mycophenolate mofetil, or cyclophosphamide. A variety of biological regimens and stem cell options are currently being explored.

Prognosis

Patients with non-organ-threatening disease who do not have antiphospholipid antibodies have a normal life expectancy. Organ involvement increases morbidity and mortality. Approximately 50% have 20-year life expectancies. The most common causes of demise

Table 1 Revised American College of Rheumatology criteria for SLE (1997)^a

Cutaneous criteria	Butterfly rash (lupus rash over the cheeks and nose) Chronic cutaneous (discoid) rash (a thick, plaque-like, adherent rash that scars) Sun sensitivity (rash after being exposed to ultraviolet A or B light) Oral ulcerations (recurrent sores in the mouth or nose)
Systemic criteria	Arthritis (inflammation of two peripheral joints with tenderness, swelling, or fluid) Serositis (inflammation of the lining of the pleura or pericardium) Neurological disorder (seizures or psychosis with no other explanation)
Laboratory criteria	Blood abnormalities (hemolytic anemia, leucopenia, thrombocytopenia) Immunological disorder (antiphospholipid antibodies, anti-dsDNA, anti-Sm, lupus anticoagulant or false-positive syphilis serology) Positive antinuclear antibody blood test

^aA person is said to have SLE if four of the 11 criteria are present at any time. Anti-dsDNA, anti-double-stranded DNA antibodies; anti-Sm, anti-Smith antibodies.

include infection, complications from accelerated atherogenesis and immune suppression, and unresponsive inflammation. For those with ongoing chronic disease, quality of life can be markedly diminished due to medication (e.g., corticosteroids), swollen joints and inflammation limiting activities of daily living, chronic pain, specific diets, sun avoidance, decreased ability to think clearly, edema from nephrosis, and cold avoidance due to Raynaud's disease, among other factors. This is associated with increased stress and decreased ability to respond to it.

The Role of Stress in the Immune Response

The role of stress in SLE has been looked at in a small number of animal models and human studies. Stress is a complex concept that involves interactions of the hypothalamic-pituitary-adrenal (HPA) axis in combination with cytokines, hormones, and the sympathetic nervous system. Patients with SLE generally manifest a blunted HPA axis response and relative glucocorticoid resistance. The latter has been documented by the larger doses needed to achieve a therapeutic effect in managing lupus, smaller numbers of glucocorticoid receptors on cells, and defectively functioning or mutated glucocorticoid receptors. Chronic inflammation is associated with hypercortisolism. In addition, prolactin is an established acute-phase reactant. Levels are increased in up to 20% of lupus patients, and this hormone can also increase interferon and interleukin (IL-)2 production.

Recently, there has been considerable interest in the role of cytokines in SLE. Lupus mice have diminished IL-1 receptor expression, and lupus patients have increased serum IL-6 levels that correlate with flares. Cerebrospinal fluid levels of interferon α are elevated in lupus psychosis. The release of these glycoproteins is a well-documented stress response. The release of cortisol is also associated with increased sympathetic

nervous system activity. The autonomic nervous system is dysfunctional in lupus, as well established by Raynaud's phenomenon and vasomotor instability (e.g., palmar erythema). This has been correlated in the disorder with the increased release of neuropeptide Y.

In summary, lupus patients have a sluggish corticotropin releasing hormone (CRH) response, relative glucocorticoid resistance, and hypercortisolism suggestive of an adaptive response to chronic inflammation. Cytokine and hormonal imbalances along with dysautonomia serve to perpetuate this.

Clinical Implications of Stress in Lupus

Lupus is associated with substantial emotional and societal costs. It has been suggested that up to half of all lupus patients have psychiatric comorbidities such as dysthymia and depression. This section reviews whether stress can induce or exacerbate lupus and how it can be managed (Table 2).

Various studies have shown that emotional stress and physical trauma can affect the immune system by causing decreased lymphocyte mitogenic responsiveness, lymphocyte cytotoxicity, increased natural killer cell activity, skin homograft rejection, graft-versus-host response delayed hypersensitivity. Could the impairment in T-cell immune functions be related to a clinical flare mediated by B-cell hyperreactivity? Acute stress in SLE has been purported to correlate with increased urine neopterin levels, IL-4 levels, decreased natural killer cell response, and increased β_2 -adrenoreceptors on mononuclear cells without a clinical disease flare.

Can Emotional Stress Induce Lupus?

As early as 1955, crises in interpersonal relationships were associated with the onset of disease. Up to one-half of all lupus patients interviewed believe that stress is associated with its initial presentation. Unfortunately, no evidence-based study has documented

Table 2 Stress in SLE – summary^a

Sluggish CRH response, relative glucocorticoid resistance, and hypercortisolism suggestive of an adaptive response to chronic inflammation

Cytokine abnormalities, hormonal dysfunction, and dysautonomia perpetuate this response

Physical trauma can produce cutaneous lupus; no evidence-based studies have shown that physical or emotional trauma can induce SLE

Evidence-based studies have documented that physical trauma and emotional stress can aggravate SLE, although concomitant fibromyalgia is confounding factor and strict guidelines of abnormalities occurring within 60 days of a specific incident have been published for litigation purposes

Stress-reduction measures include antidepressants, anxiolytic agents, biofeedback, cognitive-behavioral therapy, and counseling.

^aCRH, corticotropin releasing hormone.

this. Patients with SLE possess autoantibodies several years prior to diagnosis, according to a serum repository kept by the U.S. Armed Forces. Many patients manifest an undifferentiated connective tissue disease (UCTD) for years prior to evolving into frank SLE. (UCTD is defined as inflammatory arthritis or Raynaud's with a positive ANA or rheumatoid factor in an individual who fails to meet the ACR criteria for lupus or rheumatoid arthritis. One-third of patients evolve SLE or rheumatoid arthritis, one-third remain UCTD, and one-third have spontaneous resolution of their symptoms.) The mechanisms resulting in this transformation are not known.

Can Emotional Stress Exacerbate Lupus?

At Harvard University, of 45 flares in 160 patients over a 40-year period, 41 patients associated these exacerbations to emotional stressors. Lupus patients may have significantly reduced cell mobilization to psychological stress compared to controls. Several surveys have subsequently shown that stress can elevate antinuclear antibody levels and be associated with clinical flares. Life-event stress predicted adverse changes in functional disability over a 6-month period in one study and self-reported daily stressors were associated with increases in clinical activity in three others. These studies did not take into account the impact of quality of life related to steroid therapy for lupus or the confounding influences of fibromyalgia, which is present in one-third of all lupus patients.

Can Physical Trauma Induce or Exacerbate Lupus?

Cutaneous skin lesions seen in lupus may be found after physical trauma, lacerations, and scars. Sometimes these scars evolve into skin cancers. Two studies, on the other hand, suggested that major physical trauma such as an earthquake is not associated with disease flares but may actually improve the process. The physical trauma of a motor vehicle accident is also associated with myofascial injuries, and no published study has associated this with a lupus flare. Guidelines for documenting a lupus flare after trauma have been published and include the following findings within 60 days of the event: (1) increased symptoms and physical signs of lupus documented in a progress note, (2) worsening of inflammatory laboratory parameters (e.g., sedimentation rate or anti-DNA), (3) increases in lupus medication or new anti-inflammatory medication ordered by the practitioner, and (4) introduction of psychotropic medication prescribed by the treating physician or referral to a psychologist documenting increased stressors. The patients medical record over the prior year can be used as a historical control.

Management of Stress in Systemic Lupus Erythematosus

Stress-reduction measures include managing the inflammation associated with disease activity, counseling, pain management, cognitive-behavioral therapy, and anxiolytics and antidepressant medications. Counseling usually emphasizes improved coping, cognitive therapy, and biofeedback; improving resilience; managing stress, and regulating mood. Controlled studies have validated this approach.

Stressors in Teaching
Teacher Burnout
Burnout as a Process

Glossary

<i>Burnout</i>	A state of physical, emotional, and mental exhaustion that results from long-term involvement with people in situations that are emotionally demanding.
<i>Emotional exhaustion</i>	Feelings of being emotionally overextended and drained by others.
<i>Depersonalization</i>	A callous response toward people who are the recipient of one's services.
<i>Cynicism</i>	An indifferent or distant attitude towards one's work.
<i>Lack of personal accomplishment</i>	A decline in one's feelings of competence and successful achievement in one's work with people.
<i>Social support</i>	The exchange of information leading a person to believe that he or she is cared for. It can also involve provision of information, tangible help, or emotional help.
<i>Role conflict</i>	The interference of the efforts to fulfill the demands associated with one role with the efforts to fulfill the demands associated with other roles.

Stressors in Teaching

It is well documented that teaching is a highly stressful occupation. Several writers have noted recurring demands in the teaching environment that lead to significant levels of stress and burnout in teachers. There are several sources of stress for teachers. One of the most frequently acknowledged stressors for teachers centers around students. Problems with students include disruptive behavior, such as verbal and physical abuse; emotional demands of students; their special needs; and their heterogeneous in abilities – all of which tax the time and energy of an already busy teacher. Another major stressor for teachers involves the conflicting demands made by supervisors, colleagues, students, and the students' parents. A third set of stressors in teaching relates to teachers' workload itself, mainly their work overload. Quantitative work overload involves too many demands on teachers with too little time in which to meet these demands adequately. Often it is accompanied by feelings of being rushed and impatience. The importance of work overload as a stressor is underlined by the fact that teachers themselves in countries all over the world have consistently cited work overload as a major stressor in their job. Important dimensions associated with work overload are excessive paperwork, lack of preparation time for class, making reports, and submitting grades. Having to meet constant deadlines throughout the year, including those associated with grading, tests, exams, and written reports by students is cited as another major stressor by teachers. Oversized classes with either inadequate or no teaching assistance also function as stressors in teachers.

Additional stressors associated with teaching are found at the administrative level. A frequently cited administrative stressor is the exclusion by the administration of teachers from decision making that bears directly on their workload and the quality of their work life. Research has shown that when teachers do not have the opportunity to participate in the school's decision-making processes, their morale, motivation, self-esteem, and job satisfaction are more likely to decline. Lack of recognition of teachers' professional accomplishments by supervisors and school administrators alike contributes to an increase in stress levels in teachers. When teachers experience high role conflict in their jobs, role ambiguity, and low autonomy, they are more likely to experience stress. At the administrative level, additional stressors include inflexible employment policies on staffing and leave, and poor communication with teachers. Thus, research has demonstrated that teaching is associated with a wide range of stressors, including those intrinsic to teaching, those involving the relationship between teacher and student, and those related to the organizational structure of the school including the school administration.

Teacher Burnout

Considerable research worldwide has examined psychological consequences of stress in teachers. Over time, the cumulative effects of stressors lead to a decrease in job satisfaction, reduced commitment to teaching, absenteeism, and job turnover. At the individual level, greater stress is associated with an increase in somatic complaints and with physical and psychological illness. Research has shown that the experience of stress over time often leads to burnout in teachers. Although burnout is linked to occupational stress, burnout goes beyond stress by emphasizing the accumulation of the effects of stressors within a context that emphasizes total life and environmental experiences. Research findings indicate that teacher burnout in several Western industrialized countries has increased and affects a significant and growing proportion of teachers. Burnout is often defined as a state of physical, emotional, and mental exhaustion that results from long-term involvement with people in situations that are emotionally demanding. Because individuals who enter teaching are often presented with work pressures in addition to teaching, they often find themselves in situations that are heavily demanding. Research shows that human service professionals, including teachers, are particularly vulnerable to burnout. Freudenberger's original idea of burnout was that workers would

find themselves under increasing pressure to help others, would demand more of themselves than they were able to give, and would ultimately exhaust themselves.

Measurement of Burnout

Given the significance of burnout for the individual, it is necessary to have a standardized instrument to measure it. The Maslach Burnout Inventory (MBI), developed by Christine Maslach and Susan Jackson in 1986, is currently the research instrument used most widely to measure burnout. The MBI has three subscales that measure three different aspects of burnout. These are emotional exhaustion, depersonalization, and reduced personal accomplishment. Emotional exhaustion is defined as feelings of being emotionally overextended and drained by others. Depersonalization is a callous response toward people who are the recipient of one's services.

Lack of personal accomplishment is a decline in one's feelings of competence and successful achievement in one's work with people. The need for developing a scale that measures burnout in occupational groups other than human service professionals prompted the development of the Maslach Burnout Inventory-General Survey (MBI-GS) in 1996. Thus, the MBI-GS defines burnout as a crisis in one's relationship with work, not necessarily as a crisis in one's relationship with people. In the MBI-GS, the depersonalization scale is replaced with a scale measuring cynicism, an indifferent or distant attitude toward one's work. Research findings show that teachers are vulnerable to burnout in all three areas. For example, teachers show emotional exhaustion when they perceive they are unable to give of themselves to students as perhaps they did earlier in their careers. Depersonalization and cynicism occur when teachers develop negative, cynical, and sometimes callous attitudes toward students, parents, and/or colleagues. Feelings of diminished personal accomplishment occur when teachers perceive themselves as ineffective in helping students to learn and in fulfilling other school responsibilities. For individuals who experience burnout, one of the first reactions is distancing themselves from the job. Burnout has also been linked to job turnover, absenteeism, poor performance, and various types of individual distress symptoms including depression, anxiety, and somatization. Overall, burned-out teachers are likely to be less sympathetic toward students, have a lower tolerance for classroom disruption, be less apt to prepare adequately for class, and feel less committed to their work.

Gender Differences and Burnout

One question that has been raised by many researchers regarding teachers is: who is more burned out, women or men? Research findings from a variety of studies conducted in several different countries show that men have significantly greater levels of depersonalization than women. Why should men be more prone to depersonalization, an attitude characterized by callousness and being impersonal toward one's students? One explanation is found in accepted norms associated with the masculine gender role, which emphasizes strength, independence, separation, and invulnerability. In this context, depersonalization may be regarded as a reflection of men's repressed emotionality. Described in this way, depersonalization may be seen as an ineffective coping form that allows men to continue their work with people yet remain untouched in any significant way by others' suffering. Moreover, it is through the distance they have imposed between their students and themselves that men can remain uninvolved, thus appearing callous. It is also possible that depersonalization is a result of an inability on the part of men to cope with work strain. Because it is socially unacceptable for men to openly express vulnerability, men have fewer options for emotional expression. Higher depersonalization in men has been associated with lack of collegiality, higher absenteeism, greater medication use, and a lower quality of life.

Another explanation for women's lower depersonalization compared to men focuses on women's greater ability to cope with interpersonal stress. Women have an edge over men in dealing with the emotional strain of people work because the feminine gender role emphasizes caring, nurturance, and concern for others. As a result, women may be less likely than men to respond to troubled individuals in an impersonal and callous manner. Some researchers have found that women have higher scores than men on emotional exhaustion. Women may experience greater emotional exhaustion because, compared to men, their total workload (including paid and unpaid work) is higher. Although the number of men doing housework and childcare has increased in recent years, according to research findings women still do most of the work in the home. Further research has shown that women's increased workload interferes with their ability to wind down from a stressful day, with resultant negative effects on their health. Research also shows that women experience greater role conflict (between work and family roles) than their male counterparts. Related findings indicate that there are different predictors of burnout in men and women. In women role conflict between home

and work roles is a significant predictor of burnout, whereas in men the predictors of burnout tend to be confined to work. A structural explanation of gender-related differences in burnout highlights the association of role conflict with stress and burnout in women. It is widely recognized that employed women, including teachers, typically maintain major responsibility for the home and the family, and thus more often than men, bear the burden of role conflict.

Burnout, Stress, Social Support and Coping

Over the years, researchers have investigated several ways that burnout in teachers can be reduced, including individual and social forms. Many of the social forms involve interventions that have led to lower burnout levels in teachers by changing the work environment or reducing burnout at its source (i.e., in the workplace). Specific examples include teacher involvement and participation in the decision making undertaken by the school; facilitating the development and provision of social support; and improving supervision through the clarification of work goals, which has resulted in less role ambiguity and lower role conflict in teachers. Burnout can be reduced by establishing clear lines of authority and responsibility in helping to reduce ambiguity and conflict. With teachers, it may be valuable to solicit their input in areas that affect their work life in order to gain greater involvement and commitment. The development of social support among teachers can be achieved by providing adequate time and location interaction. Encouraging the development of mentoring relationships between older and younger teachers can also be useful in increasing commitment among teachers. Considerable research has demonstrated the effectiveness of social support in lowering burnout and stress levels in teachers. Social support is the exchange of information leading a person to believe that he or she is cared for. It can also involve the provision of information and tangible, practical, and/or emotional help. Research suggests that social support may be effective in reducing burnout directly or as a buffering agent. When there is a direct effect, social support is positively related to physical and psychological health, regardless of the presence or absence of work stressors. Social support may also moderate the impact of stress on burnout so as to assist people with high stress to cope better. The buffering argument suggests that stress may affect some people adversely but that those with social support resources are relatively resistant to the deleterious effects of stressful events.

Several studies report that teachers with high burnout perceive less social support in their school

environment than those with lower burnout levels. Teachers' perceptions of stress are reduced by perceived support, particularly from school staff, including colleagues. Further research findings indicate that teachers who work in an environment that they perceive as being supportive are less likely to experience high levels of stress and burnout. Research by Greenglass and co-workers indicated that support from a teacher's peers or coworkers are the most important buffers of burnout. As suggested by Pines, social support in the form of technical advice such as helping teachers find more successful and innovative ways of working with students, may be a particularly effective intervention for burned-out teachers. Coping may also lead to lower levels of burnout. For example, in a 2002 study of burnout in German teachers, the relationship between proactive coping and burnout was examined. In this study, 316 German teachers were surveyed and job burnout was defined three-dimensionally in terms of emotional exhaustion, depersonalization, and lack of personal accomplishment. Proactive coping is multidimensional and forward-looking. It combines autonomous goal setting with self-regulatory goal attainment cognitions. Proactive coping integrates processes of personal quality of life management with those of self-regulatory goal attainment. The results showed a significant pattern of decreasing burnout with increasing levels of proactive coping. High-proactive-coping teachers reported less emotional exhaustion, less depersonalization, and more personal accomplishment than low-proactive-coping teachers.

Burnout as a Process

Increasingly, research has focused on the examination of burnout as a process that develops over time. As such, researchers have been interested in discovering the paths through which burnout develops. Some researchers have demonstrated the existence of two separate paths to burnout: a cognitive path, manifested in personal and professional feelings of lack of accomplishment, and an emotional path, reflected in a sense of overload and emotional exhaustion. It is generally held that the process begins to develop with external stressors, such as disruptive students, excessive paper work, and conflicting demands, which lead to emotional exhaustion. Emotional exhaustion is considered the aspect of burnout that is most responsive to the nature and intensity of work stressors. Some researchers refer to emotional exhaustion as the prototype of stress. In general, various job conditions are more strongly related to emotional exhaustion than to the other two subscales,

depersonalization and lack of personal accomplishment. Emotional exhaustion is predicted mainly by occupational stressors, such as work overload, inadequate use of skills, and interpersonal conflicts. In addition, emotional exhaustion is considered the affective component of burnout that leads to depersonalization or cynicism. Through depersonalization, individual teachers attempt to cease the depletion of their emotional energy by treating their students as objects rather than people. Emotional exhaustion can also lead to reduced feelings of personal accomplishment in the teaching role, which may be seen as indicative of an impoverishment of people's perceptions of themselves in their work role, particularly as teachers. Findings suggest that depersonalization contributes to lower feelings of accomplishment as well. Because effective teaching is contingent on teachers' communicating with students on a personal level, teachers may be particularly vulnerable to low feelings of accomplishment when perceiving that they are treating their students impersonally, as in the process of depersonalization. Other findings point to the consistency of each of the burnout components over time. Emotional exhaustion, depersonalization, and lack of personal accomplishment predict significantly the scores on the same scales 1 year later, according to Greenglass and co-workers. Researchers agree that burnout levels are fairly stable over time.

One of the advantages of viewing burnout as a process over time is that it allows the investigation of the antecedents of burnout, particularly those associated with the school, the teachers' interpersonal relationships, and their workload. Being able to specify the antecedents of burnout in teachers has both theoretical and applied value. By specifying variables that contribute to burnout, theoretical knowledge of the process of the development of stress and burnout is advanced. On a practical level, it is valuable to the school's administration to be able to specify just what causes burnout. Examining the development of stress and burnout over time offers the possibilities of changing the processes involved and grappling with the complex causal relationships. This presumably can lead to the development of better and more effective intervention techniques, which can improve teacher morale and prevent the harmful consequences of further burnout.

Glossary

<i>Heterothermy/ poikilothermy</i>	The pattern of temperature regulation in a species in which the variation in core temperature, either nychthemally or seasonally, exceeds that which defines homeothermy.
<i>Homeothermy</i>	The pattern of temperature regulation of a given species in which the cyclic variation in core temperature, either nychthemally or seasonally, is maintained within arbitrarily defined limits despite much larger variations in ambient temperature.
Q_{10}	The ratio of the rate of a physiological process at a particular temperature to the rate at a temperature 10°C lower, when the logarithm of the rate is an approximately linear function of temperature.

Temperature change has striking effects on many physiological processes. All chemical reactions in an organism, including the processes of metabolism, are temperature-dependent. Within certain limits, an increase of temperature accelerates most physiological processes, such as the rate of oxygen consumption, which can be regarded as an expression for the overall metabolic activity of an organism. The rate of a physiological process usually increases with temperature in a regular manner. In oxygen consumption, for example, a rise of 10°C in temperature may cause a twofold or even threefold increase. The increase in the rate of a metabolic process caused by a 10°C increase in temperature is called the Q_{10} of this process. **Figure 1** shows an example for a given physiological process with a Q_{10} of 2. For a 10°C interval, the Q_{10} is thus defined as the ratio of the rate of the metabolic process (R_1) at a particular temperature ($T + 10$) to the rate (R_2) at a temperature 10°C lower (T), when the logarithm of the rate is an approximately linear function of temperature.

$$Q_{10} = R_1(T+10)/R_2(T)$$

According to van’t Hoff’s rule, the Q_{10} for thermochemical reactions is between 2 and 3, and so are the Q_{10} values for metabolic processes in an organism.

Animals can be divided into two groups: poikilotherms and homeotherms. The term poikilotherm

Figure 1 Temperature dependence of a given metabolic process. For this process, a temperature increase of 10°C results in the doubling of the rate of the process ($Q_{10} = 2$).

means that an animal shows a large variability of body temperature as a function of ambient temperature. In homeothermic animals (birds and mammals, including humans), the variations in body temperature are maintained within narrow limits despite much larger fluctuations in ambient temperature. This means that in poikilotherms the rate of metabolic processes is strongly influenced by temperature changes according to van't Hoff's rule. Van't Hoff's rule applies to homeotherms in the same way, but it is masked by other effects. The direct effects of changing temperatures on the metabolic processes within homeotherms are prevented by temperature regulation, the prerequisite to preventing large fluctuations of body temperature. As a consequence, the vital processes of poikilotherms depend entirely on external temperature conditions, whereas homeotherms live at practically the same level of intensity during the entire year and in all climatic regions. The geographic distribution of homeotherms is thus not as limited as the distribution of poikilotherms. Note that, in reality, the distinction between homeothermy and poikilothermy is not as clear-cut as the definitions of these terms suggest. On the one hand, many poikilothermic animals show rudimentary signs of temperature regulation, especially by behavioral means and, to a certain extent, even by metabolic responses. On the other hand, a number of homeothermic animals sometimes permit a profound fluctuation of body temperature (e.g., hibernators), with strong temporary restrictions of their vital processes.

In spite of their ability to regulate body temperature, large fluctuations in ambient temperature represent stressful conditions for homeotherms, especially when

people or animals are exposed to temperatures that are out of their thermoneutral zone. For humans, the thermoneutral zone, or zone of thermal indifference, is defined as the range of ambient temperatures associated with specific water vapor pressure, air velocity, and radiant exchange within which 80% of active people do not complain of the thermal environment. A number of behavioral, physiological (functional), and morphological strategies with regard to the thermoregulatory system have developed to reduce the strain that is imposed on homeotherms by pronounced external temperature changes. These strategies can be summarized as thermal adaptations. Morphological adaptations, such as changes in body shape and insulation, need from months to years to develop unless they are genetically fixed and appear seasonally. In general, they are preceded by functional (physiological) modifications, including changes in the capacity of thermoregulatory effector systems and regulatory characteristics that need much less time to develop. One of the best-investigated changes in the capacity of thermoregulatory effector systems is the development of nonshivering thermogenesis in the brown adipose tissue of small mammals during cold adaptation. An increase in maximal sweat rate, and thereby in the capacity to dissipate heat, during adaptation to heat has also been described. The development of increased capacities of heat production and heat dissipation takes place within several weeks. Short-term physiological adaptations to stressful external temperatures consist of changes in thermoregulatory characteristics, which can be defined as deviations in the threshold and the gaining of the thermoregulatory responses. For example, a short exposure to a cold environment evokes not only thermoregulatory reflexes and emergency reactions but also a temporary shift of the shivering threshold to a lower mean body temperature. Continuous confrontation with a cold environment for several weeks results in an even more pronounced shift of the threshold for heat production to a lower body temperature. Similar adaptive changes of thermoregulatory characteristics occur in response to short- or long-term exposure to heat.

Introduction

Effects of Terrorism on the Terrorist

Effects of Terrorism on Victims

The Effect of Terrorism on Society

Glossary

<i>Anomie</i>	The sense of isolation that comes from lack of social integration and cohesion.
<i>Posttraumatic stress disorder (PTSD)</i>	A psychological injury characterized by reexperiencing trauma, hyperarousal, and withdrawal.
<i>The Troubles</i>	A term used to describe the 30 years of civil unrest and paramilitary campaigns, bordering on civil war, in Ireland.

Introduction

The *Oxford English Dictionary* defines terrorism as the use of violence and intimidation for political ends. This definition could apply to any kind of warfare. However, the term terrorism usually refers to unconventional tactics of warfare used by a less powerful group against a more powerful adversary. In this way, the Roman legions encountered terrorism in the woods of Germany. As a tactic, it has become more successful with the development of technology, so that a small number of terrorists with modern weapons can do a great deal more damage than many men wielding swords and halberds. The extent to which a small number of highly motivated men can inflict catastrophic pain on a mighty enemy was demonstrated by the events of September 11. Terrorism as a tactic is increasingly attractive to groups who lack political or military power.

One man's terrorist is another man's freedom fighter, and terms such as commando, guerrilla, partisan, and paramilitary help to confuse the picture further. At the same time, many former terrorists have been accepted into the political mainstream, and the progression from terrorist leader to statesman seems to be the rule rather than the exception

(e.g., Nelson Mandela). Other terrorist organizations become increasingly involved in organized crime, and the pattern of terrorism is moving away from organized political groups to small, very extreme groups and even to individuals (e.g., the Uni bomber and the cell structure of the IRA and various Islamic fundamentalist groups). The field of terrorism, then, is a complex one, with the spectrum including a wide variety of separate phenomena.

Effects of Terrorism on the Terrorist

There has been little research from Northern Ireland examining the psychological profiles of active members of terrorist organizations. During the Provisional Irish Republican Army hunger strikes, hunger strikers were assessed and found not to be suffering from any psychiatric illness. Their self-harm was deemed to be a political act. Anecdotal information from professionals working in the prisons in Northern Ireland, suggests that various terrorist organizations are associated with different types of motivation and, hence, with different psychological profiles. For example, the members of some terrorist organizations are reputed to be very calm, calculating, politically motivated individuals, with very few of the traits that would normally be described as personality disorder. In contrast, the members of other organizations (particularly those organizations with an interest in organized crime) tend to have psychological profiles more typical of violent criminal offenders.

There is no evidence from Northern Ireland suggesting that those who engage in terrorist violence are more likely to be psychiatrically ill than members of the general population. Indeed, it seems that those who perpetrate terrorist violence, as a rule, tend to escape psychologically unscathed. Some individuals are troubled by their conscience, and the general public would like to believe that those who commit particularly horrific crimes will be troubled by these crimes for the rest of their lives. In general, however, it seems that 10 years after a horrific violent crime it is the victims and the bereaved who will wake up screaming in the night, whereas the perpetrator sleeps soundly.

There are positive psychological aspects that help to motivate terrorists. The terrorist act can act as a form of catharsis, relieving feelings of anger and frustration that have often built up over many years. At the same time, terrorists usually see themselves as martyrs. This is a constant theme, from the blood

sacrifice of Patrick Pearse in 1916, to the ideas of martyrdom among Islamic suicide bombers today.

These positive aspects are, for the terrorist, balanced by the threat that he or she poses to family and friends, the fear of living in secret, and the ultimate fear of losing his or her life. Thus, a young man who is considering becoming a terrorist is contemplating a tactic that is both highly effective and highly costly.

Effects of Terrorism on Victims

The effects of terrorist violence on victims has been described in detail (see **Northern Ireland, Post Traumatic Stress Disorder** in). Research performed with survivors of violence in Northern Ireland indicates that normal individuals subjected to extreme terrorist violence are likely to develop posttraumatic stress disorder (PTSD) and that normal individuals who are bereaved by terrorism are likely to develop a grief reaction. We use arbitrarily defined time points to describe the syndromes of delayed and chronic PTSD and to define delayed and chronic grief reactions. However, all of these psychological injuries, which happen to normal people put under intolerable strain, fall within a continuous spectrum, ranging from a psychological upset lasting a few days to symptoms that can be lifelong.

Vulnerable individuals may also be the victims of terrorist violence. Under these circumstances, the violence can act as a nonspecific stressor or life event precipitating an episode of psychiatric illness. For example, individuals prone to depression or anxiety may develop an anxiety neurosis or depressive neurosis if exposed to violence. Clearly terrorist violence has a devastating effect on the lives of those exposed to it, whether they are psychologically vulnerable or not, resulting in incapacitating physical and psychological injuries, as described by the work of Curran and colleagues, among others, working in Northern Ireland.

A high percentage of individuals who experience serious violence develop PTSD. Studies across the world, looking at different types of traumatic incidents, indicate that between one-quarter and one-half of individuals who experience serious trauma develop PTSD. It seems that the key factor in developing this condition is the fact of being made aware of one's own mortality at a very deep level. For this reason, it seems that it is the individual's perception of the event that causes the psychological injury, and because of this, different individuals can respond differently to the same type of trauma. For example, if two friends are caught up in a terrorist bomb blast, one might develop PTSD and the other might escape relatively

unscathed. For the same reason, similar traumatic events may affect the same individual differently at different times. For example, a bus driver may be hi-jacked at gunpoint on four occasions without developing any psychological problems, only to develop severe PTSD when hi-jacked for a fifth time under virtually identical circumstances.

Anyone who has been exposed to serious violence may develop the core symptoms of PTSD, namely reliving the incident, hyperarousal, and emotional constriction. These core symptoms are seen after a wide variety of traumatic situations in different parts of the world. In addition to the core symptoms, an individual may develop a number of additional symptoms under specific circumstances. In situations of terrorist violence, hostage taking and torture are unfortunately frequent occurrences. This type of prolonged trauma tends to result not only in PTSD but can also in a syndrome similar to learned helplessness. Individuals recovering from traumatic events of this kind often experience profound symptoms of depression. Survivors of hostage taking often have these symptoms mixed with feelings of relief to be alive and a paradoxical gratitude to their captors for allowing them to live.

One common form of terrorist violence in Northern Ireland has been assassination attacks on the security forces launched from private houses. In these attacks, families are often held at gunpoint overnight while an ambush is set up. Families who experience these attacks often develop symptoms of PTSD associated with symptoms of depression and learned helplessness. The situation is complicated further by a group of symptoms that are often seen after burglaries. These symptoms include obsessional cleanliness and a feeling that the home has been violated, making it difficult to relax in the house where these events occurred.

Free-floating anger and irritability are core symptoms of PTSD. After natural disasters or tragedies for which no one is to blame, this free-floating anger often takes the form of irritability, and the survivors of natural disasters often direct their anger and hostility toward those closest to them. In the case of terrorist violence, there is a natural focus for this free-floating anger and victims understandably direct their anger toward the terrorist organization. In some circumstances, this can be helpful because there is less tendency for anger to be directed inward or toward other family members.

Individuals who have suffered terrorist violence in their own homes find it very difficult to recover from their psychological injuries while they continue to live in the environment where the trauma occurred. Every time they walk into a certain room they are reminded

of the violence that occurred there. At the same time, survivors of this type of violence often feel so much anger toward the perpetrators of the violence that they are determined not to be forced out of their homes. They refuse to run away. This appears to be a decision of principle, but it can tend to delay the natural healing process. Security lights and alarms are a nightly reminder of the violence that took place in the home. Those individuals who swallow their pride and move to a new environment often recover more quickly from their psychological injuries.

Even after the paramilitary ceasefires in Northern Ireland, there have been a number of terrorist incidents, most notably a bombing outrage in the town of Omagh in which large numbers of civilians were killed. This incident, in particular, generated a number of research studies on PTSD and specifically on the treatment of PTSD. As a result, the Department of Health in Northern Ireland produced the *CREST Guidelines for the Management of Post Traumatic Stress Disorder in Adults* in June 2003. This advice highlights the importance of cognitive-behavioral therapy (CBT) and eye movement desensitization, along with symptomatic treatment with antidepressants.

The Effect of Terrorism on Society

The effects of terrorist violence on a society are rather more difficult to define. As mentioned earlier, terrorism can take many forms, from the organization of mass protests and violence to individual attacks on selected targets. Curran and colleagues have pointed out that the form of civil violence over the years in Northern Ireland changed from mass disturbances, affecting large numbers of people, to more surgical attacks on selected targets, affecting only a very small number of victims. Community studies, examining indicators of mental health, have failed to demonstrate a greater psychiatric morbidity among the population of Northern Ireland. This has been explored in some detail by Cairns and Wilson, who examined various indicators of psychiatric morbidity, including psychiatric admission and referral rates, suicide and attempted suicide, substance abuse, clinical studies, and community studies. The overall impression is that during The Troubles it was remarkably difficult to demonstrate a higher level of psychiatric morbidity among the general population of Northern Ireland. Loughrey and coworkers postulated that this may have been because of the changing nature of violence in Northern Ireland to more selective targeting. The victims of violence, although affected severely, were perhaps too small in number to be detected by community surveys.

In the early years of The Troubles, Lyons described a year by year decrease in the suicide rate in Northern Ireland with the outbreak of civil violence. He believed that this might be explained by Durkheim's theory of anomie. In the late 1800s, Durkheim predicted that, during periods of war, suicide rates would decrease because the aggression of the population was being externalized toward a common enemy. This prevented aggression from being directed inward in the form of self-harm. Lyons's original results seemed to support this. However, when the suicide rates in Northern Ireland were examined over a more extended period of time by Curran and colleagues, it was found that the increase in the suicide rate at the start of The Troubles, observed by Lyons, may have simply been part of a wide year-to-year random variation. Durkheim's theories pertaining to social cohesion may still be relevant, however. Curran and coworkers postulated that the detrimental effect on the mental health of a small number of victims directly affected by terrorist violence might be balanced by a beneficial effect of polarizing sectarian community spirit on a larger number of marginalized individuals within society at large. In other words, although the direct victims of violence suffer greatly, they are small in number in most urban terrorist campaigns. At the same time, polarized sectarian communities, such as those in Northern Ireland, though deplorable in many ways, may paradoxically offer increased social support to marginalized individuals from within their own community. It is difficult to test this hypothesis, but most psychiatrists in Northern Ireland will be aware of some patients whose level of psychological functioning seems to be improved because of the increased social cohesion of the frontline communities in which they live.

Presumably the function of terrorism is to evoke terror. Initially, terrorists in Northern Ireland seemed to have been singularly unsuccessful in this regard. The terrorist campaign went on so long that the population of Northern Ireland viewed the risk of terrorist violence as just another of the statistical risks that face us when we get out of bed each morning. It almost seems that there is a homeostatic mechanism in the human psyche with regard to risk, such that exposure to risk develops tolerance. This seems to apply to risk of all sorts. The population of the Western world has become surprisingly blasé about the risks associated with motor vehicles, despite the huge carnage produced by these machines on our roads. Similarly, most individuals within society accept the risk of violent crime when they leave their homes. These mechanisms for living with risks appear to be largely based on denial and associated with thoughts such as "it will never happen to me."

Some groups within Northern Ireland, such as members of the security forces who are particularly at risk of terrorist violence, develop a gung-ho culture, where risk is denied completely. This is often associated with substance abuse in order to maintain the high levels of denial. There is a saying in Northern Ireland: "You can get used to anything." In the same way that money does not make you happy, it seems that terror does not necessarily make you afraid.

A number of studies within Northern Ireland have demonstrated a rebound of psychiatric morbidity after the declaration of the various terrorist cease-fires. However, this increase in psychiatric morbidity appears to be relatively short-lived. It may be that the atmosphere of peace allows people to come forward and seek help for psychological problems that they had chosen to ignore while the violence was continuing. The reaction of the community to terrorist violence can be seen as mirroring an individual's reaction to trauma. In traumatic circumstances, many individuals continue to function in a calm, detached manner while the violence is occurring, only to find themselves breaking down some hours later after they have had time to think about the dangers of the situation. This seems to be a natural adaptive mechanism. When survival is the first priority, individuals get on with what needs to be done at the time. They postpone thinking about the horror of the situation until it is safe to do so. It seems that societies function in a similar way, using denial mechanisms in order to continue functioning. However, the reality of the situation comes flooding in when peace is restored, resulting in the rebound of psychiatric morbidity.

Terrorism is here to stay. Just as individuals become inured to violence and tend to return to the state of normal denial, so societies learn to live with the chronic risk of terrorist violence and it becomes just one of the many risks in a modern world. When this happens, terrorism no longer succeeds in evoking terror. It becomes a less powerful tactic, and it

becomes less likely that young men and women will be prepared to pay the terrible price of becoming terrorists.

In summary, the effects of terrorist violence are not as we would imagine them to be in a fair world. Most active participants in violence are psychologically unscathed. The lives of victims are often devastated, whereas the level of psychological morbidity in a community exposed to terrorism is lower than might be expected. In the end, the damage done by terrorism to a community appears to be spiritual rather than psychological.

Thermal Environments

Physiological Mechanisms of Heat Exchange

Metabolic Heat Production

Response Patterns to Sustained Thermal Stress

Other Environmental Factors Influencing Thermal Stress

Pathophysiological Consequences of Thermal Stress

Thermal Stress Not Due to Exposure

Glossary

Acclimatization

Autonomic or behavioral changes occurring within an organism that reduce the strain caused by stressful changes in the natural climate. Acclimation refers to the adaptive changes that occur within an organism in response to experimentally induced changes in a particular climatic factor (e.g., ambient temperature) in an artificial, controlled environment.

Autonomic temperature regulation

The regulation of body temperature by involuntary thermoeffector responses to heat and cold that modify the rates of heat production and heat loss. Autonomic in this sense does not mean that all responses are controlled by the autonomic nervous system.

Body heat balance

The steady-state relation in which the heat produced by the body equals that lost to the environment.

Brown adipose tissue (BAT)

A particular form of adipose tissue with selective distribution that differs both structurally and functionally from white adipose tissue. Its main role appears to be regulatory thermogenesis. Its activity is controlled by the sympathetic nervous system and various humoral factors, especially catecholamines.

Core temperature

The mean temperature of the thermal core (i.e., the interior of the body), usually represented by the temperature of a particular internal site, for example, rectal or oral.

Thermal strain

Any deviation of body temperature induced by sustained thermal stress that cannot be fully compensated by

temperature regulation. Also, any activation of thermoeffector activities in response to thermal stress that causes sustained changes in the state of other, nonthermal regulatory systems.

An organ system and its function that affect heat balance in a controlled manner as part of the processes of temperature regulation.

Thermoeffector

Thermal Environments

Thermal stress is defined as any change in the thermal relation between a temperature regulator and its environment that, if not compensated by thermoregulatory effector reactions, will result in hyper- or hypothermia. A temperature regulator, thus, is an organism that has the capacity to appropriately activate coordinated, autonomic, and/or behavioral heat conservation or loss (thermolytic) and heat production (thermogenic) effectors such that its body (core) temperature (T_c) remains relatively stable even in thermal environments that, *a priori*, might be expected to cause T_c to rise above (hyperthermia) or fall below (hypothermia) its normal range. Animals that possess this capability are called homeotherms. The condition in which T_c is within ± 1 SD of its normal range is termed cenothermy. The thermal environment in which neither the mechanisms for extra heat production (e.g., shivering) nor for extra heat loss (e.g., sweating) are activated is termed the thermoneutral zone; under these conditions, the T_c of healthy subjects at rest does not vary more than $\pm 2^\circ\text{C}$ around its 24-h mean. Acute exposure to an environment warmer than thermoneutrality results in more heat being gained from the environment than lost to it; conversely, more heat is lost than produced by the body on exposure to an environment cooler than thermoneutrality. From a thermal physiological point of view, inactive humans are tropical animals when naked, thermoneutrality being an ambient temperature (T_a) of $28\text{--}30^\circ\text{C}$. Thermal stress, therefore, begins as soon as T_a is higher or lower than this range. However, homeotherms may be heat-stressed at low T_a if they are active.

Physiological Mechanisms of Heat Exchange

The unavoidable consequence of heat (or cold) exposure is that unless more heat were lost from the body

(or conserved and produced by it), the body-heat balance could not be maintained and, hence, an excessive rise (or fall) of T_c could potentially occur. However, the relative stability of T_c under most thermal conditions indicates that both heat production and heat loss are regulated and that, furthermore, temperature sensors exist throughout the body that measure its temperature continuously. In the skin, the detection of warm and cold sensations has recently been ascribed to the activation of specific, temperature-activated transient receptor potential ion channels (thermoTRPs) located within the free endings of cutaneous sensory nerves. The nature of the internal body thermosensors are not yet clarified. This information is transmitted to the brain, where it is integrated and transduced into signals to thermoeffectors that are then activated so that appropriate countermeasures are initiated. These responses involve both behavioral and autonomic processes. The former modulate primarily the effective heat-exchanging surface above the skin and are expressed by volitionally or instinctively changing the skin's microclimate (e.g., by postural changes, moving to a different thermal environment, or wetting the skin). Behavioral adjustments generally precede autonomic responses; they are more economical energetically and, often, sufficient. Autonomic adjustments involve factors below the skin. They control the patency of the small arterioles that deliver blood (i.e., heat) to the surface by means of sympathetic vasoconstrictor and vasodilator systems and various cotransmitters. When open (cutaneous vasodilation), the warm arterial blood passes through these, warming the skin. As long as the skin temperature remains higher than the ambient, heat is dissipated into the environment. Conversely, when these channels are closed (cutaneous vasoconstriction), the bloodstream is conveyed through deeper arteriovenous anastomoses such that heat does not reach the surface so readily, reducing the skin-to-ambient temperature gradient and conserving body heat. This is aided further by the fact that the deep, larger vessels of the limbs lie in parallel so that warm arterial blood flowing toward the periphery passes close to cooler, returning venous blood flowing in the opposite direction, thus allowing heat to be transferred by countercurrent heat exchange from the arterial to the venous flow. This pre-cools the arterial blood, thereby contributing to increasing the thermal insulation of the extremities.

When ambient temperature exceeds skin temperature, the body gains heat. Under these conditions, the only means by which heat can be dissipated is by evaporation. For this purpose, animals that possess eccrine sweat glands activate them; those that do not, pant. The efficacy of this process is dependent directly

on the ambient and skin vapor pressure difference; that is, when the ambient relative humidity is high, little evaporation occurs. Sweating is much more expensive metabolically than cutaneous vasodilation. It also results in large losses of water and sodium, which are potentially dangerous.

Metabolic Heat Production

The heat released when the organism is resting at thermoneutrality is called obligatory nonshivering thermogenesis (NST-O); it is derived from the metabolic activity of the body. T_c is maintained within its narrow range by the controlled loss of heat from this activity. The skeletal muscle mass makes up the greatest mass of the body (~45%), but at rest it produces only 18% of the NST-O. However, more energy and, hence, heat are expended when the muscles actively contract, in direct proportion to the external work done (e.g., as in exercise). However, if no external work is performed by the contracting muscles, most of the energy expended is given up as heat. This is, in fact, what occurs in a cold environment by means of shivering. However, shivering is fatiguing, not terribly efficient (~11%), and cannot be sustained indefinitely. Another thermogenic process that does not involve muscular contractions, namely thermoregulatory nonshivering thermogenesis (NST-T), is activated in such cases. The principal effector organ of NST-T is BAT. Its thermogenic capacity is derived from the collapse of the electrochemical proton gradient normally generated by cellular respiration, limiting adenosine triphosphate synthesis, the energy currency of the body. Consequently, the energy expended is given up as heat and conducted to the numerous vessels permeating this tissue and is convected by the bloodstream throughout the body. A specialized protein, uncoupling protein 1 (UCP1, or thermogenin), present in the mitochondrial inner membrane of BAT adipocytes, facilitates this process when activated by the sympathetic nervous system. BAT NST-T is particularly prominent in neonates, but recedes with age and size. It develops over time in cold-exposed adult rodents and other small animals. In neonates and small animals, NST-T and shivering are meshed reciprocally.

Response Patterns to Sustained Thermal Stress

If a person remains exposed, unprotected, for a prolonged time to the natural climate, he or she would be at risk of eventually becoming physically exhausted from the continuous shivering in the cold or dehydrated and hyponatremic from the extensive sweating

in the heat. To prevent such noxious results, the body institutes thermoadaptive modifications that reduce the physiological strain caused by prolonged stressful thermal exposures. These adaptations, termed acclimatization, occur over an extended time course, measured in days and longer. The gradual replacement of shivering by NST-T in long-term cold exposure of small animals has already been mentioned. This type of response is called metabolic adaptation. Some homeotherms react to prolonged cold by entering into a state of lethargy called hibernation. Adult humans acclimatize to cold by using appropriate behaviors (clothing, heaters, etc.). The autonomic analog in most animals is the growth of thicker fur and the deposition of subcutaneous fat (insulative adaptation). Inadequately insulated, chronically cold-exposed humans may also develop a lower T_c and a lesser fall in skin temperature (i.e., a warmer skin; hypothermic adaptation) in time.

In long-term heat exposure, the sweat glands develop the capacity to secrete more water and sooner (i.e., they become activated at a lower threshold T_c over time); the amount of salt lost in sweat from the body also is reduced. These effects can be achieved by 1–4 h of heat exposure for 5–7 days and are mediated by the increased secretion of antidiuretic hormone and aldosterone; thirst is also stimulated. The process is facilitated by physical exercise, which, by itself, enhances the sweat rate, and persists as long as the heat exposure continues; afterward, it gradually wanes. Analogous to hibernation in the winter, some homeotherms enter into a state of summer lethargy called estivation. During moderate chronic heat exposure, the onset of both sweating and skin vasodilation occur at a higher T_c (hyperthermic adaptation).

Systemic adaptation to thermal stress also extends to the cellular level (thermotolerance). Thus, cells within the body core (e.g., exercising skeletal muscle) or in its shell (e.g., skin cells) that are acutely exposed to intense, but not lethal, heat or cold react to these stressful stimuli by producing specialized proteins (heat shock and cold shock proteins) that serve to protect them against a subsequent, otherwise potentially lethal heat or cold exposure. In contrast to heat or cold acclimatization, however, thermotolerance develops rapidly (within hours) but is temporary (3–5 days).

Other Environmental Factors Influencing Thermal Stress

In nature, a variety of factors are present that aggravate the risk of thermal stress occurring sooner than due to a T_a change alone. These include water, due to

its high thermal conductivity (beneficial in the heat, detrimental in the cold, as in wet-cold, e.g., chilblains and immersion foot); blowing wind (windchill factor), by thinning the thickness of the thermal boundary layer, a thin film of warmed air that surrounds the body (beneficial in the heat, detrimental in the cold); and barometric pressure, by affecting heat exchange by convection (reduced at high altitude) and evaporation (enhanced at high altitude) and by affecting the partial pressure of atmospheric gases (e.g., the metabolic response to cold is reduced at altitude). Other environmental factors, such as the relative humidity and the intensity of solar radiation, also contribute to the imposition of thermal stress.

Pathophysiological Consequences of Thermal Stress

During periods of heavy sweating, a strain is imposed on the heat-exposed individual's homeostatic systems that, if not properly compensated, can cause the development of symptoms (heat illnesses). Similarly, when the various defense reactions are inadequate to cope with the stress of cold exposure, severe local tissue injury (cold injuries) may develop. The risks of hypo- and hyperthermia were mentioned earlier. The susceptibility to thermal stress increases with age.

Thermal Stress Not Due to Exposure

Thermal stress may also occur due to factors not involving exposure. For example, as already mentioned, exercise can induce heat stress by increasing the rate of heat gained (i.e., produced) in excess of that lost. Conditions of decreased or increased T_c may be induced, even in thermoneutrality, by drugs that impair normal thermoregulatory functions (iatrogenic hypo- or hyperthermia), by idiosyncratic drug reactions (e.g., malignant hyperthermia), or secondary to underlying illnesses that compromise the body's thermoregulatory mechanisms (e.g., peripheral vascular disease, paralysis, or endocrinopathies). Fever, however, is not a thermal stress because it represents a regulated, deliberate T_c rise resulting from the active operation of thermogenic effectors and not the unavoidable consequence of the passive gain of heat in excess of the capability of active thermolytic effectors to dissipate it; it is a defensive response to the invasion of the body by infectious pathogens. A regulated fall in T_c also occurs, particularly in rodents exposed to toxic chemicals and hypoxia/ischemia; it protects the afflicted host from the consequent pathological effects of these insults.

Concluding Remarks

Glossary

Adaptation/
habituation

A modification of regulatory processes taking place during prolonged or repeated exposure to extreme ambient temperatures.

Poikylothermy
(PKT)

The typical metabolic condition of ectothermic animals that use external sources of heat to increase body temperature. In endotherms, a status similar to PKT can be observed in extreme ambient conditions or under pharmacological treatment with ethanol or volatile anesthetics.

<i>Thermoneutrality (TN)</i>	A range of ambient temperatures. Within the TN range, it is not necessary for the organism to activate warming or cooling mechanisms to keep the core body temperature constant. The TN range is different in different species and strains. Furthermore, there is a high degree of interindividual variability, and these differences could be related to differences in diet, age, and body weight. A TN range can be determined experimentally by measuring O₂ consumption as an indirect index of the rate of oxidative metabolism. More precise analysis requires biocalorimetry measurements to determine heat production (HP) and heat exchange (HE) in the different regions/tissues/cells of the body. Because rapid eye movement (REM) sleep is also sensitive to the ambient temperature, the TN range can be determined by measuring the total REM sleep time (longer in the TN zone).	cause intracellular HP. In the presence of uncouplers, HP is proportional to O₂ consumption, percentage of uncoupling effect, mitochondrial membrane potential, and duration of the effect.
<i>Thermopreferendum</i>	The temperature (T) range selected by microorganisms or animals placed in a thermocline. The association of a certain T range with the presence of food or memory of previous ambient conditions can influence the selection by the organism. Behavioral tests based on the resetting of the thermopreferendum can be used to demonstrate T set point shifts.	
<i>Thermoresistance</i>	Hormonal, metabolic, and cardiovascular reactions to environmental temperature changes that allow the organism to keep a constant control on core body temperature in the presence of unfavorable ambient conditions.	
<i>Thermosensitivity</i>	Capacity to respond to temperature changes. Thermosensitive (Ts) neuronal units modify the number of pulses per minute in response to small changes in temperature. Based on the response to direct warming or cooling procedures, warm-sensitive (pulses/10 min = $Q_{10} > 1.2$) or cold-sensitive ($Q_{10} < -0.6$) neurons can be distinguished, respectively.	
<i>Thermotolerance</i>	Mechanisms of adaptation that allow survival in extreme ambient conditions, for example, short-term changes in heat production and vascular control of heat exchange and long-term changes in membrane composition and insulation capacity.	
<i>Uncoupling effect</i>	When the protonic gradient across the inner membrane of mitochondria is partially or totally dissipated and heat production (HP) takes preference over ATP production. Uncoupling proteins and uncoupling agents (e.g., dinitrophenol)	

This article briefly reviews the mechanisms controlling heat production (HP) and heat exchange (HE) in endotherms (in mammals in particular) able to adapt to different, and sometimes extreme, environmental conditions. Hibernation (and estivation) represents a classic example of extreme control on thermoregulation. When food is scarce, lowering the core body temperature (CBT) allows the survival of small mammals and reptiles with minimal energetic costs. Introductory concepts on temperature (T) control in endotherms are also given.

Temperature Control

Temperature (T) control or, better, the control of the effects of T is a vital need for every cell type, even for prokaryotic organisms, given that protein conformation and membrane integrity are jeopardized at freezing, as well as at higher than 40°C temperatures (in aqueous environment that prevails *in vivo*). Exceptions to this rule in cryobiology require non-aqueous solutions. In bacteria, adaptive changes associated with small T variations (Δ : 2–10°C) always involve changes in cell membrane composition and involve the rapid induction of enzymes such as fatty acid desaturases. *Escherichia coli* responds to small changes in T by altering its growth rate, swimming behavior, and thermotaxis. Several membrane proteins (methyl-accepting chemotaxis proteins) are involved in the control of these events. The thermo/chemoreceptors are reversibly methylated at specific glutamate residues located in the C-terminal cytoplasmic domain and point mutations at the methylation sites can even invert bacterial thermotaxis. Nematodes (e.g., *Caenorhabditis elegans*) possess specific thermosensory neurons and interneurons organized in a network controlling thermotaxis. When placed in a thermal gradient, they display the ability to recognize and select the region where T is similar to the T at which they were cultured previously. Curiously, it is possible to distinguish between a cryophylic and a thermophylic behavior by selective laser ablation of one of the two interneurons controlling thermotaxis or by null mutations of either of two homeobox genes, *lin-11* or *ttx-3*, respectively. The neural circuit that regulates the response to changes in T in *C. elegans* has been characterized in detail. It consists of a thermosensory organ (neuron), two interneuronal populations, and motor neurons. Vertebrates

(amphibians and reptilians), such as lizards or frogs, exhibit a thermopreferendum when placed in a thermocline even if they are poikylothermic and thus unable to keep their core body temperature (CBT) constant in the same thermal gradient.

Only mammals and birds (warm-blooded animals) have developed a complex net of neurological, hormonal, cardiovascular, and metabolic systems that are able to keep a constant control on the CBT despite geographical, seasonal, or even diurnal differences in air T and water T. The possibility of keeping CBT constant represents an important step from an evolutionary point of view. At the cellular level, it implies that the rate of enzymatic reactions, membrane properties, and electrical excitability remain rather constant (and can be optimized) despite dramatic changes in heat production (HP) and heat exchange (HE) caused, for instance, by motor activity or cold exposure. In general, homeothermy may be one of the key evolutionary factors that have allowed uterine growth of fetuses and nocturnal motor activity.

Temperature Control in Homeotherms

Several homeostatic mechanisms allow the maintenance of a constant CBT in warm-blooded animals exposed to different ambient temperatures (AT): (1) the hormonal control on basal metabolic rate (BMR) (short term) and body mass (long term), (2) the hypothalamic/spinal neuronal network setting and controlling CBT, (3) the sympathetic and parasympathetic neuronal systems activated alternatively to govern effector mechanisms to warm or cool the body, and (4) the steady-state bulk of energy expenditure represented by the activities of muscular and adipose tissues.

Thermoresistance

Basal Metabolic Rate

When compared to poikylothermy (PKT) in animals of equal body mass, homeothermy requires the maintenance of higher BMR, with higher food intake and higher O₂ consumption. Indirectly, this means that homeotherms actuate behavioral and dietetic changes, adjusting food intake to seasonal T changes in order to guarantee sufficient energy storage. We should distinguish between (1) resting (basal) metabolic rate (MR; the heat produced is also called obligatory thermogenesis, T_g) and (2) inducible MR (the heat produced is also called facultative T_g). The resting MR can be largely modified by slow mechanisms of adaptation, whereas the inducible MR is activated quickly in order to react effectively to cold exposure. The major ways used to increase T_g rapidly are

uncoupling of oxidative phosphorylation in mitochondria (nonshivering T_g) and muscular shivering. BMR in mammals is correlated positively to the ratio of body surface to body mass; animals with a higher surface/mass ratio require exponentially more energy to keep their CBT in the range of 36–37°C.

These dramatic differences in BMR should be considered when studying the adaptive mechanisms developed by different species to allow survival in extreme conditions. Thus, for example, the drastic reduction of CBT that accompanies hibernation is advantageous for small animals (e.g., squirrels) because they save much more energy proportionally than larger animals, such as bears. Passive mechanisms of thermotolerance, such as the reduction of HE because of increased insulation, do not modify the BMR. They simply expand the range of AT compatible with survival. Food digestion is another source of T_g, and different species change their diets in relation to the amount of heat required in different seasons.

Hormonal Control on Basal Metabolic Rate

The thyroid hormones, thyroxine (T₄) and triiodothyronine (T₃), play a central role in controlling cellular ATP levels, MR, and T_g during both fetal and adult life. T₃ and T₄ increase obligatory T_g and work in synergy with catecholamines to trigger facultative T_g. Furthermore, thyroid hormones are involved in embryogenesis, particularly in the differentiation of brown fat tissue (BAT). Studies have clarified the molecular mechanisms sustaining the different metabolic effects and the modulatory actions of thyroid hormones on insulin, glucagon, growth hormone, and adrenaline effects. Thyroid hormones enhance or suppress gene transcription via the specific interaction with different nuclear receptors. The effects of T₃ and T₄ on T_g are related to the induction of several classes of proteins that include uncoupling proteins (UCPs); FAD-linked glycerol-3-phosphate dehydrogenase, a carrier transferring electrons from NADH to ubiquinone in complex I in the respiratory chain of mitochondria; and adenine nucleotide translocase, the ATP/ADP exchanger, which is also present in the inner mitochondrial membrane, where it controls the concentration of phosphate acceptor (ADP).

Table 1 shows genes whose expression is known to be under the control of thyroid hormones. UCP-1 protein expression is induced in rat BAT by cold exposure and suppressed by fasting; and T₃ increases UCP-1 production both by increasing gene transcription and by stabilizing mature UCP-1 mRNA. In BAT, local control of the relative levels of T₃ and T₄ is maintained via the presence of thyroxine 5'-deiodinase. This cold-inducible enzyme converts T₄ to the

Table 1 Genes involved in induction of thermotolerance or thermoresistance under the transcriptional control of thyroid hormones^a

Mitochondrial proteins	FAD-dependent glycerol-3-phosphate dehydrogenase (ATP/ADP exchange activity)
	Tom20: outer membrane receptor
	Matrix heat shock protein 70
	Adenine nucleotide translocase (ATP/ADP exchange activity)
	Acyl-CoA oxidase
	Na ⁺ K ⁺ -ATPase (α and β subunits)
	Acetyl-CoA carboxylase
	Uncoupling proteins (UCP-1,-2,-3)
	ATP-dependent protease
Hormones	Renin
	Steroidogenic acute regulatory protein
	Oxytocin
	Prepro-TRH (negative control)
Other enzymes	Cholesterol-7 α -hydroxylase
	Malate dehydrogenase (negative control)
	Cytochrome P450 (negative control on CYP4A1, CYP4A3, and CYP4A23)
	Ca ²⁺ -ATPases (in sarcoplasmic reticulum: SERCA1 and SERCA2)
	Phosphoenolpyruvate carboxykinase
Membrane receptors and ion channels	Glucagon receptor
	β 1 and β 3 adrenoreceptors
	Potassium channels: Kv1.2, 1.4, 1.5, 2.1, and 4.2 α subunits
Nuclear factors	Steroid receptor coactivator-1
	Cold-inducible coactivator of nuclear receptors
Others	Glucose transporter GLUT4
	Myosin isoforms
	Phospholamban: a major target of the β -adrenergic cascade in the heart

^aSERCA, sarcoplasmic reticulum Ca²⁺ ATPase; TRH, thyrotropin-releasing hormone.

more potent T₃, thereby locally modulating the ratio between T₃ and T₄ levels. In muscles, thyroid hormones also control the expression of genes coding for myosin isoforms, the Na⁺-K⁺-ATPase pumps, and the Ca²⁺-ATPase channels of the sarcoplasmic reticulum, sustaining, in this way, muscular performance during shivering.

Thyrotropin (TSH) production in the pituitary gland and, upstream, thyrotropin-releasing hormone (TRH) production in several hypothalamic and raphe nuclei control the synthesis and secretion of thyroid hormones. TRH also seems to exert additional actions in the suprachiasmatic nuclei (SCN), amygdala, lateral septal nuclei, and pineal gland. These actions are always related to chronobiological changes of the MR. During hibernation, the levels of thyroid hormones, TSH, TRH, and their receptors are decreased in all of the just-mentioned brain regions (except for TRH levels in the pineal gland).

In recent years, pharmacological therapies have been proposed to increase HP in obese patients, with special attention to the hypothalamic systems controlling the balance between energy storage and energy expenditure. Interesting observations were made in *ob/ob* and *db/db* obese mice, which lack the control of leptin (the starvation hormone) on adipose tissue metabolism. These animals exhibit a CBT that is 1–2°C below normal; several studies point to the

almost total impairment of nonshivering T_g present in *ob/ob* torpid animals from the first days of life. This is probably due to (1) the defective regulation of thyroxine 5'-deiodinase, (2) the attenuated UCP mRNA expression in BAT during cold exposure, (3) the higher circulating levels of corticosterone observed in *ob/ob* mice, and (4) the increased sensitivity of these animals to leptin. Moreover, leptin can affect thermogenesis, modulating the sympathetic outflow directly as it activates neurons that coexpress cocaine- and amphetamine-regulated transcript (CART) and pro-opiomelanocortin (POMC) neurons that innervate sympathetic preganglionic neurons in the thoracic spinal cord. One of the hypothalamic nuclei constitutively expressing high levels of the leptin receptor long form is the arcuate nucleus. This nucleus contains NPY-glucose sensitive neurons, which represent a possible key link between leptin and T control because pro-NPY mRNA expression is inhibited by leptin and the direct injection of NPY into the anterior or dorsomedial hypothalamus causes deep hypothermia.

Hypothalamic and Brain Temperatures

Thermosensitive (Ts) neurons are present in the anterior brain stem of several endothermic vertebrates and even in ectotherms, further confirming a role for these neurons in the CBT control from a very

early stage in the phylogenetic scale. In mammals, the local warming or cooling of hypothalamic (anterior preoptic, among others) and spinal regions triggers panting, autonomic responses, and muscular shivering, respectively. Ts neurons are also activated by remote thermal stimuli. Approximately 25% of the neurons in anterior hypothalamus are Ts, and Ts neurons can also be found in various nuclei involved

in thermal control (**Figure 1**), circadian rhythms (SCN), and sleep induction (diagonal band). The hypothalamic temperature (HT) plays a key role in the control of the CBT. The hypothesis of HT as an independent variable controlled locally and tightly, integrating peripheral and extrahypothalamic stimuli, is further sustained by the observation that T undergoes smaller fluctuations in hypothalamus

Figure 1 Schematic view of the principal thermosensory afferent and efferent systems in the rat brain. a, Afferent pathways; b, main descending efferent pathways. Hypothalamic regions and autonomic nuclei involved in core body temperature control are highlighted in a sagittal section of the hypothalamic/bulbar region. In a, periventricular hypothalamic organs – subformal organ (SFO) and organum vasculosum lamina terminalis (OVLT) – are also indicated; their projections to the preoptic and paraventricular nuclei control the thermogenic response to circulating hormones. The suprachiasmatic nucleus (SCN), the principal circadian clock of the body, receives light information from the retina and projects to the autonomic division of the paraventricular nucleus. In b, the main hypothalamic descending efferent pathways control thermogenesis via the activation of the autonomic system. NTS, nucleus of the solitary tract; VMN, ventromedial nucleus.

than in other brain and trunk regions in response to several different stimuli. For instance, during hibernation, HT is set approximately 6–10°C higher than CBT. It is generally believed that local hypothalamic and brain heating is controlled by cardiovascular mechanisms, dependent on blood T and perfusion. Several studies were able to demonstrate that mammalian species can decrease the T of the brain below the T of the blood circulating in the large arteries of the trunk. This effect, namely selective brain cooling (SBC), is possible because of the presence of a carotid thin-walled rete that keeps the arterial blood in close contact with the cooler venous blood of the cavernous sinus. What is really under control is the T of the venous blood, which can be modified (sphincter of the angularis oculi vein), allowing the entrance into the sinus of venous blood coming from the upper respiratory tract and the facial vein. The activation of mechanisms of SBC is dependent on CBT and is usually evident when CBT is approximately 40–41°C. Again the onset and the degree of the effect are determined predominantly by T signals of hypothalamic origin. Although the carotid rete is not present in humans, several groups have suggested that SBC could also play a critical role in controlling brain T in humans, at least during physical activity and prolonged exposure to the sun. Endotherms, and mammals in particular, can count on a tight endocrine control of the HT set point, which can be modified in response to infection (fever), sleep, circadian and ultradian rhythms, pregnancy, and fertility cycles. The interaction among different stimuli is possible because of the multimodal response of Ts neurons to endogenous pyrogens, estrogens, glucose levels, osmolarity, and blood pressure, among other stimuli.

Autonomic System and Temperature Control

The major hypothalamic, bulbar, ganglionic, and spinal nuclei involved in the control of autonomic response during thermal stress are depicted in [Figure 1b](#). Sympathetic activation can cause an immediate reduction of skin blood flow in thermoregulatory vessels, piloerection, heat production in BAT, muscular shivering, and increased respiratory rate. Parasympathetic control, however, is exerted mainly on exocrine sweat glands and cardiovascular and respiratory systems, respectively. The sympathetic system exerts a tight thermoregulatory control via the rhythmic and tonic activity of postganglionic neurons, whereas the integration of spinal and bulbar inputs is controlled by preganglionic neurons. Furthermore, every peripheral nerve contains silent units that can be activated in the presence of stress stimuli such as heat.

Adaptive changes in parasympathetic activity after physical exercise, especially in hot environments,

cause bradycardia and increased exocrine sweat gland activity. In normal individuals, 2–4 million sweat glands are able to secrete approximately 3 l of hypotonic fluid/h. In athletes or acclimated people, the sweating rate is higher and starts as soon as there is heat load because of the lowered threshold of sweating response in hypertrophic glands.

Nonshivering Thermogenesis

In children and in many animal species, the major source of heat is BAT. The main role in heat production in BAT adipocytes is played by the mitochondrial protein thermogenin (UCP-1). UCP-1 may represent up to 15% of the total protein content of the inner mitochondrial membrane, and during 1 week of cold exposure the total content of UCP-1 in rat intrascapular BAT rises from 60 to approximately 300 µg, whereas the total protein content increases little. It has been calculated (using *in vitro* microcalorimetry) that 1 kg of stimulated BAT can produce approximately 300 W of heat energy. The amount of BAT, and of vessels supplying O₂ to the tissue, can be increased trophically during acclimation processes. Heat production in BAT is obtained by dissipation of the protonic gradient across the inner mitochondrial membrane. Studies indicate that the fatty acid shuttle of protons is responsible for this effect. The system is under the control of β₃ receptor activation in several species.

The general assumption of a lack of nonshivering T_g in adult humans has to be considered in light of the discovery of UCPs other than the BAT-UCP-1; UCP-2, UCP-3, UCP-4, and BMCP-1 are expressed differentially, mainly in the white adipose tissue, liver, heart, glycolytic muscles, and brain (UCP-4 and BMCP-1 are brain-specific). Structurally, these proteins are similar to other mitochondrial carriers, such as the oxoglutarate carrier. [Figure 2](#) shows a probable phylogenetic tree of this class of proteins based on the available cDNA sequences of UCPs from various species. Putative proteic sequences from *C. elegans* and yeast suggest the presence of these proteins also in lower evolutionary levels organisms. The analysis of the different UCP cDNAs shows that UCP1, UCP4, BMCP1, and plant UCPs possibly represent a more recent step from the evolutionary point of view, whereas UCP-2 may be phylogenetically older. The comparative analysis of the structure of the available UCP genes supports this hypothesis further in that the UCP2 gene does not contain a TATA box and is constitutively expressed and rather ubiquitous. UCP-2 and UCP-3 genes are contiguous, suggesting possible mechanisms of gene duplication. Tissue levels of the different UCP gene products are under translational control. Their expression is correlated with changes

Figure 2 Phylogenetical tree of the uncoupling protein family(ies). The discovery of plant mitochondrial uncoupling protein (PUMP), of UCP-like proteins in *Arabidopsis thaliana*/potato, and of several novel mammalian uncoupling proteins suggests that the ancestral UCP gene has probably evolved prior to the divergence into animals and plants. This is also confirmed by the presence of a protein with uncoupling activity into the mitochondria of *Acanthamoeba castellanii*, a nonphotosynthetic protozoan, which in molecular phylogenesis appears on a branch basal to the divergence points of plants, animals, and fungi. The phylogenetic tree was obtained using the GCG software package.

in ATP production (lowered), inner mitochondrial membrane potential (lowered), and heat production (increased). However, their functional role in T_g is still under debate. UCP-2, UCP-4, and BMCP-1 mRNA expression in the brain and UCP-2 mRNA expression in the spleen, lymph nodes, and thymus suggest other possible physiological roles. Furthermore, UCPs are regulated differentially (possibly in a tissue-specific manner). The different affinity for free ATP/ADP and GTP/GDP nucleotides (inhibitors) could cause the activation of uncoupling at different metabolic states. Possible differences in terms of affinity to fatty acids and the influence of pH on nucleotide binding still require further characterization.

Muscular Shivering

Shivering is controlled by motor neurons and is caused by the repetitive contraction of both extensory and flexory muscles with a frequency directly proportional (on a logarithmic scale) to BMR. The Renshaw interneuron activation is responsible for the synchronization of motoneurons and for the upper discharge frequency. During cold exposure, more than one-third of the total heat produced can come from shivering, and muscular performance is dependent on the intracellular levels of several cold-inducible proteins, such as the carrier for glucose uptake into muscles (GLUT-4) and sarcoplasmic or endoplasmic reticulum Ca^{2+} -ATPases, respectively. Massive shivering

also allows a prompt reaction to intraoperative hypothermia or raises the CBT quickly to mount very high fevers (e.g., during renal infections).

Thermotolerance

Membranes

All cells possess the ability to modify the fluidity of the membranes in order to preserve structural and functional integrity in the presence of T changes. In poikylothermic animals, cold exposure increases the percentage of polyunsaturated fatty acids (mono- and polyunsaturated, mostly oleic acid) in phospholipids and the relative amount of phosphatidylethanolamine (PE) (vs. phosphatidylcholine, PC). These changes in the composition of the phospholipid bilayer preserve fluidity, probably because unsaturated fatty acids increase membrane disorder (homeoviscous adaptation). It should be noted that cold adaptation causes similar changes in the composition of the mitochondrial membrane in BAT with an increase in polyunsaturated fatty acids and PE and with a decrease in cholesterol content. The final effect is probably a greater membrane fluidity. The brain of hibernating animals contains less cholesterol and greater amounts of both PC and PE, mono-unsaturated fatty acids, arachidonic acid, and polar gangliosides.

Enzymes and Cryoprotective Polypeptides

The most impressive effect of hibernation is the drastic reduction of BMR. This effect is obtained by a tissue-specific inhibition of the activity of key metabolic enzymes such as pyruvate dehydrogenase. In some cases, a different phosphorylation state of the enzyme has been involved (6-phosphofructo-1-kinase); in other cases, the nonspecific effect of temperature change on the K_m for the different substrates seems to be sufficient to explain the observed effect. However, there is much more to learn in relation to cryophylic or thermophylic enzymes if, for instance, in cold-adapted microorganisms, isoforms of proteins such as α -amylase or lipase exhibit high catalytic efficiency in the range of 0–30°C.

Both heat and cold exposure causes the tissue-specific expression of heat shock proteins (HSP70, HSP110, and HSP25). They function as molecular chaperones mediating the folding, assembly, or translocation across intracellular membranes of several polypeptides. Heat shock proteins also play a role in protein degradation and are required for repairing the damage resulting from stress. A subzero-tolerance mechanism, which has evolved in organisms adapted to low temperatures, is the expression of extracellular

antifreeze proteins (AFPs). At least five structurally distinct AF (glyco) proteins have been identified; they all inhibit ice crystallization efficiently.

Thermosensitivity

A breakthrough in the field of peripheral thermosensation/thermonociception has been the cloning and characterization of a vanilloid receptor (VR1) present in somatic and visceral sensory neurons, trigeminal nucleus caudalis, nucleus of the solitary tract (NTS), area postrema, and caudal medulla. The cloning of another more broadly expressed receptor form (VR-like) was reported. They both probably belong to a large family of neuronal mechanosensors (responsive to stretch). VR-1 and VR-like (functional nonselective cation channels) can be activated in a narrow range of temperatures (>42°C for VR1 and >54°C for VR-L). VR1 also responds to protons and vanilloids, even when expressed in oocytes. These studies have rekindled interest in a very large number of experimental observations obtained with vanilloids (capsaicin or resinipheratoxin) that were left without molecular explanation. Capsaicin injection in the periphery does in fact stimulate sensory neurons (nociception and thermonociception) and causes the degeneration of sensory neurons after chronic treatment.

There are, however, several reports describing central effects of capsaicin on Ts neurons. Locally applied capsaicin is, for instance, able to increase the firing rate of warm-sensitive neurons and inhibit the discharge of cold-sensitive neurons in the anterior hypothalamus, causing hypothermia. Furthermore, chronic treatments can cause the degeneration of neurons in the anterior hypothalamus. Nothing is yet known about the receptor(s) that could mediate these effects centrally.

Moreover, it is not even clear whether cellular thermosensitivity is caused by the presence of a thermosensor molecule, responding to temperature changes in the same manner as aquaporins respond to osmolarity changes and opsins to light. Studies on the intrinsic thermosensitivity of different ion channels have shown that they are affected differentially by temperature changes. Among the most studied temperature-sensitive ion channels are the *Shaker*-type, voltage-gated potassium channels (Table 2).

The neurochemical features of warm sensory fibers are partially characterized. One interesting aspect, reported by several groups, is the presence of a calcitonin gene-related peptide (CGRP) in thermosensory fibers innervating, for instance, BAT. It should also be noted that cold acclimation causes a major increase in noradrenergic-, neuropeptide Y-, substance P-, and calcitonin gene-related peptide content in nerves in

Table 2 Effect of temperature on the activity (Q_{10}) of various ion channels^a

Name	Parameters	Q_{10} temperature range ($^{\circ}\text{C}$)	System	Source ^b
K ⁺ channels				
Shaker H4	Activation time constant	+3.14 (20 to 4)	<i>Xenopus laevis</i> oocytes	1
	Decay time constant	+7.2 (20 to 4)	<i>X. laevis</i> oocytes	1
Mink	Activation time constant	+4–7	<i>X. laevis</i> oocytes	
Na ⁺ channels				
TTX-sensitive noninactivating Na current	Current amplitude	+4.3–7	Temperature-sensitive rat POA neurons	
Ca ²⁺ channels				
HVA calcium channels	Activation time constant	+10	Dorsal raphe neurons	4
	Current amplitude	+1.7	Dorsal raphe neurons	
L-type cardiac Ca channels	Inward currents	+5.8 (15 to 25)	<i>X. laevis</i> oocytes	5
HAC		+3–4		
Cl ⁻ channels				
From the <i>Torpedo</i> electric organ (slow gate)	Deactivation potential	+40	<i>X. laevis</i> oocytes	3
CFTR	Opening rate	+9.6		2

^aCFTR, cystic fibrosis transmembrane conductance regulator; HAC, human articular chondrocytes; HVA, high-voltage activated; Mink, minimal potassium ion channel; POA, preoptic area; TTX, tetrodotoxin.

this tissue. Vanilloid receptor 1 expression and CRGP production, as well as peripheral thermosensitivity, are under the control of nerve growth factor.

Concluding Remarks

Outstanding athletic performances, obtained in the presence of prohibitive ambient conditions, are reported almost daily by mass media, and every year, as usual, animals deeply modify their metabolism to survive the coming winter. The biochemistry of the cellular/neuronal control of body temperature, however, still escapes our knowledge.

We know that autonomic and hypothalamic centers play a key role in thermoregulation, and several metabolic studies have provided a large body of evidence on the extent of the control of thyroid hormones on heat production in different organs. Further important information may come from ongoing research on the metabolic effects of leptin, from the understanding of the physiological role of uncoupling

proteins, and perhaps from studies on receptors such as VR-1. The perspective looks promising, and emphasis should be placed on the multidisciplinary approach required to solve the biological problem of thermal control.

Stressors at Three Mile Island
Short-term Consequences
The Effects of Venting Unit 2
Long-term Consequences and Issues
Summary

Glossary

<i>Anticipatory stress</i>	Stress experienced as one waits and/or prepares for a stressful event. In some studies, this stress is similar to that experienced once a stressor is experienced.
<i>Disaster</i>	An unusual event of large scope that overwhelms the social system. Disasters can be of natural origin (e.g., earthquake, tornado) or of technological origin (e.g., Three Mile Island, war).
<i>Stress</i>	A psychobiological process initiated by events that threaten, harm, or challenge an organism or that exceed available coping resources. Stress is characterized by psychological, behavioral, and physiological responses that are directed toward adaptation, but can become pathological if they persist or are inappropriate.
<i>Technological disaster</i>	A powerful stressor that disrupts and overwhelms the social system and has a human origin, by either direct action (e.g., sabotage) or failure of technology (e.g., air disasters, industrial accidents). The human causes of these events introduce issues related to blame and control and may cause longer-lasting distress than natural disasters.
<i>Uncertainty</i>	A state characterized by ambiguity or lack of information pertinent to a particular situation or outcome. It is hypothesized that uncertainty is often experienced as stressful and unpleasant. Uncertainty about the extent of exposure to radiation at Three Mile Island contributed to area residents' distress.

One of the most prominent industrial disasters in United States history occurred on March 28, 1979. Failure in the core of Three Mile Island (TMI) Unit 2

resulted in the release of radioactivity into the surrounding community. For days, residents of the surrounding area, as well as people all over the nation, watched as this unprecedented nuclear accident and emergency unfolded. The accident itself was relatively brief, but uncertainty and fear about explosions and radiation release persisted for several days afterward. Authorities were unable to determine whether and to what extent residents were exposed to radiation. Poor management of the situation and conflicting reports made by authorities led to loss of trust and credibility, contributing further to uncertainty and fear among area residents. An evacuation advisory was issued for pregnant women and young children residing within 5 miles of TMI, resulting in a substantial evacuation of nearly 150 000 residents. After the initial accident and 2-week acute emergency period, the residents of the TMI area continued to deal with potentially stressful issues, such as disposal of the radioactive gas, water, and solid waste inside the reactor complex and the possible restart of the undamaged reactor at TMI (TMI Unit 1 had been shut down for routine maintenance when the accident occurred in Unit 2).

Stressors at Three Mile Island

The circumstances surrounding the disaster at TMI set it apart from other disasters such as tornados, earthquakes, and floods. Natural disasters typically cause widespread destruction of property and often involve injury or fatalities. Following the accident at TMI, however, there were no tangible negative effects, only the invisible threat of radiation and worries about its possible long-term consequences. While exposure to low-level radiation has a range of suspected effects, scientific knowledge of its effects is not well characterized. Nonetheless, many people believe that exposure to radiation causes cancers or genetic abnormalities. Area residents were uncertain about how much radiation was released during and after the accident, whether they were personally exposed to radiation, whether their exposure was sufficient to cause negative health outcomes, and whether they would develop cancer or pass on genetic defects. This occurred in the context of the loss of control suggested by analyses of human-caused disasters. The resultant stress experienced by many area residents appeared to be unusually persistent because of the continued presence of sources of new exposure and the intractability of the residents' worries about harm already done by previous exposures. The

primary stressors in the TMI environment were related to uncertainty and the life threat associated with possible consequences of radiation exposure.

Short-term Consequences

State and federal government initiatives after the accident at TMI resulted in several studies of the accident's impact on surrounding communities. In the first month after the accident, most residents reported stress and distrust of authorities, especially those residents who lived closest to the reactors, who were younger, or who were women, particularly women with preschool-aged children. Although levels of stress decreased as time passed, significant amounts of stress were still reported 9 and 12 months later, especially among residents who lived close to TMI, mothers of young children, and people who had evacuated. Residents living close to the TMI plant also reported more stress than residents living near an undamaged nuclear power plant, suggesting that it was not just the fear or distrust of nuclear power that resulted in high stress levels, but also the possible exposure to radiation following the damage at TMI.

The Effects of Venting Unit 2

While a year is usually sufficient for most people to recover from natural disasters, the events at TMI made adaptation difficult during the ensuing 12 months. Radioactive krypton gas had been trapped in the TMI Unit 2 containment building during the accident, and, beginning 16 months after the accident, officials started venting the radioactive gas directly into the environment. While the residents were assured that the amounts of radiation vented were low and safe, the venting occurred nearly every day for weeks and carried with it the threat of new contamination. Before, during, and after the venting, TMI area residents exhibited more symptoms of stress than residents living in a comparison community 80 miles away. Although there was no change in stress levels in the control sample over time, stress levels in the TMI residents decreased during and after the venting. It is possible that TMI residents were exhibiting anticipatory stress before the venting began and, once it occurred, returned to lower levels of responding. Whether this was due to an anticipatory stress response or a possible remedial effect of venting could not be addressed by available data. Regardless, TMI residents continued to experience significant stress following the venting, and by 2 years after the accident many area residents exhibited chronically elevated symptoms of stress.

Long-term Consequences and Issues

Researchers continued to follow TMI area residents during the 6-year period between the accident and restart of the undamaged TMI Unit 1 reactor. Those residents who remained in the area continued to exhibit elevated stress levels as compared to groups of people living in other communities. Negative effects were not limited to measures of self-reported distress. Heightened indicators of physiological arousal (urinary catecholamines and systolic and diastolic blood pressure), more health complaints, greater use of prescription drugs, and poorer task performance were also evident as compared to control groups. Additionally, the incident was not isolated to central Pennsylvania; people all over the country responded to the media attention given to TMI and the fears associated with use of nuclear energy and radiation exposure.

During this time, the issues surrounding the restart of the undamaged TMI Unit 1 resulted in intense legal battles that culminated in a unanimous decision from the U.S. Supreme Court to allow the TMI Unit 1 to be restarted. In October 1985, more than 6 years after the incident at Unit 2, Unit 1 was brought back on-line, despite protests from residents and serious concerns from community groups about the stress it would cause and the damage it would do to the healing TMI communities. Because there were no tangible environmental effects of the TMI Unit 2 accident, the possibility of psychological distress was not considered by the courts to be sufficient grounds for curtailing national efforts for nuclear energy use. However, data indicated that stress levels increased as the restart of Unit 1 approached, and, while stress levels appeared to decrease for some residents after the restart occurred, there was continued evidence for higher stress levels in area residents when compared to groups of people living in other communities. Additionally, evidence of chronic stress responding was still apparent in TMI residents up to 10 years after the Unit 2 disaster.

In addition to the factors described earlier (e.g., distance from TMI, having small children), psychosocial variables played a prominent role in the selective vulnerability of TMI residents to stress. People who reported higher perceived threat and worry over possible radiation exposure and its consequences, as well as loss of trust in officials and loss of perceived control, were also more likely to report higher levels of stress. In addition, those who felt they had fewer people to turn to for support and who tried to deny the situation or use active, problem-focused efforts to try to control an uncontrollable situation were more vulnerable to the effects of stress. In contrast, people

who tried to control their own negative emotions instead of the environment fared much better.

Summary

Although the residents of TMI suffered long-term stress and worry from the incident at TMI Unit 2, their experiences have taught stress researchers and government officials important lessons about the consequences of technological disasters. There is now greater awareness of the significant psychological and physical health effects that can occur following technological catastrophes, even when there is no tangible evidence of destruction. Perceived threat and other psychosocial mediators, such as loss of control and loss of trust in authorities, are sufficient by themselves to promote stress responding and its negative consequences. Additionally, the long-term follow-up of TMI residents has provided insight into the possible determinants of chronic stress responding. Factors such as the experience of unwanted, distressing thoughts about TMI and continued reminders of the possible danger are important determinants of vulnerability to long-term negative consequences. This information has prompted further research into these vulnerability factors as well as aided the development of interventions aimed at helping victims of other disasters.

Thymic Architecture and Components
Activities of the Thymus
Glucocorticoids and Thymic Function
Effects of Stress on the Thymus

Glossary

<i>Negative selection</i>	Selective inactivation of those thymocytes that express a T-cell receptor with a high avidity for self-peptide presented by self-histocompatibility complex-encoded molecules and therefore are potentially harmful to the host.
<i>Positive selection</i>	Selective survival and expansion of those thymocytes that have successfully rearranged T-cell receptor genes and express a T-cell receptor with a moderate affinity for self-histocompatibility complex-encoded molecules.
<i>Thymocyte</i>	An immature T cell undergoing the processes of differentiation and selection in the thymus prior to export to the peripheral immune system.

The thymus is a bilobed organ situated in the anterior superior mediastinum of mammals. The major function of the thymus is the differentiation and selection of T lymphocytes that will populate the peripheral immune system and function as part of acquired immunity. The thymus is critical for normal immune function and is highly susceptible to the effects of stress.

Thymic Architecture and Components

As early as the late 1800s it was thought that the function of the thymus was important to the immune system. However, it was not until 1961 when Jacques Miller demonstrated that thymectomy resulted in loss of graft rejection and compromised immunity to bacterial infection that this organ's place in the immune system began to be defined. The thymus gives rise to T lymphocytes, which are critical for normal immune function. Differentiation from immature precursors

to mature T cells occurs in the thymus in a highly organized manner that will be discussed later in the section describing thymic function. Various aspects of thymus function have been highly characterized in mice and rats; however, the majority of these observations are also characteristic of that which occurs in humans.

The thymus consists of two main areas. The cortex normally comprises about 80% of the thymus and is densely packed with thymocytes that visually obscure the cortical stromal elements. In the medulla, the cellular density of thymocytes is considerably less and the medullary stroma is more easily visible.

The thymus differentiates from the third and fourth pharyngeal pouches in mammals and is formed from ectoderm, mesoderm, and endoderm, all of which are required for normal development. The cellular components generated by these tissues comprise the thymic stroma, composed of a diverse array of epithelial cell subsets. The origin and function of these various thymic epithelial subsets are still highly debated. Other stromal elements include macrophages and dendritic cells that are of hematopoietic origin. The cells that ultimately differentiate into T cells are derived from pluripotent hematopoietic stem cells that migrate into the thymus from either the fetal liver or bone marrow. Evaluation of the T-cell component in the adult thymus reveals significant heterogeneity. Differentiative stages of thymocytes can be determined via cell surface markers, the most characteristic of which are the expression of CD4 and CD8 and T-cell receptor (TCR) (Figure 1). The earliest thymocytes compose only a small fraction of the total T-cell number (1–5%) and express Thy-1, but do not express CD4, CD8, or TCR (double negative, DN). The population of highest frequency, composing 80–85% of thymocytes, expresses both CD4 and CD8, along with moderate levels of TCR (double positive, DP). The most mature thymocytes, poised to emigrate to the peripheral immune system as functional T cells, are the single positive (SP) cells that express either CD4 (~10%) or CD8 (~5%), along with high levels of TCR (comparable to that observed on peripheral T cells).

Activities of the Thymus

T-Cell Differentiation and Selection

The major activity of the thymus is to harbor T cells during their differentiative stages and to select functional T cells that can be exported to the peripheral

immune system. Stem cell entry occurs about gestational day 11 in the mouse (gestation is approximately 20 days). Initially, colonization occurs by penetration of the thymic capsule, although later, the influx of stem cells occurs through the high endothelial venules (HEV) that enter the thymus at the cortico-medullary junction. Stem cells migrate out toward the subcapsular cortex where they give rise to the first thymocytes around gestational day 15. The earliest thymocytes that arise are the DN cells. Rearrangement of T-cell receptor genes to generate receptors of unique antigen specificity, similar to that which occurs in B cells for the generation of immunoglobulin, begins early, and by day 15 of gestation the first cells expressing the TCR $\gamma\delta$ chains ($\gamma\delta$ T cells) appear. These cells migrate out of the thymus rapidly and, for the most part, are replaced with other thymocytes expressing the conventional TCR α and β chains. Rearrangement of the TCR β chain genes significantly precedes rearrangement of TCR α chain genes, and generation of a functional rearranged and expressed β chain is required for progression to the next stage of T-cell development. Once the β chain is expressed on the cell surface as a component of the pre-TCR complex, signals associated with this expression turn off any further rearrangement of the β chain, allowing extensive proliferation and differentiation to DP thymocytes, while turning on rearrangement of the TCR α chain genes. Successful rearrangement of the TCR α locus results in moderate level expression of TCR on these DP thymocytes. It is at this point that thymocytes undergo rigorous selection processes (Figure 1).

One might ask why thymocytes are sequestered in the thymus during differentiation and selection. The answer to this question may reside in the manner by which T cells recognize antigen via their TCR. Unlike immunoglobulin on B cells, which bind a three-dimensional structure on an antigen, the TCR binds processed fragments of antigen that are located in a groove on self major histocompatibility encoded molecules (MHC). Therefore, TCR recognition of antigen is constrained by the fact that the TCR must have affinity not only for the foreign peptide but the entire peptide/self-MHC complex. Because the specificity of the TCR is generated randomly during rearrangement of the TCR gene fragments, it is easily understandable that a large portion of T cells may generate receptors that have little or no affinity for self-MHC and therefore would be useless to the immune system. However, the specificity of a randomly generated TCR may have a very high affinity for self-peptide/MHC complexes and would be considered autoreactive and detrimental to the organism. It is unclear exactly what percentage of DP thymocytes express nonfunctional (as deemed by lack of affinity

Figure 1 Thymocyte differentiation and selection. (A) Schematic diagram of thymocyte populations expressing CD4 and CD8. The earliest thymocytes (1–5%) express Thy-1 but not CD4, CD8, or TCR (double negative, DN). Double positive cells (DP) compose 80–85% of thymocytes and express both CD4 and CD8 along with moderate levels of TCR. The most mature thymocytes are the single positive (SP) cells that express either CD4 (~10%) or CD8 (~5%) along with high levels of TCR. (B) Progression and localization of thymocyte differentiation. DN cells, localized in the subcapsular cortex, differentiate to become cortical DP expressing detectable levels of TCR on their cell surface. At the DP stage, thymocytes undergo selection to eliminate cells expressing autoreactive receptors and enrich for cells expressing a TCR with moderate affinity for self-MHC. These positively selected cells differentiate further to express either CD4 or CD8 with high levels of TCR on their surface. These medullary thymocytes go on to populate the peripheral immune system.

to self-MHC) versus autoreactive TCRs, but it is clear that greater than 90% of thymocytes generated never leave the thymus. Therefore, a major function of the thymus is to cautiously screen developing thymocytes within a controlled environment to obtain those thymocytes of greatest functional potential while eliminating unnecessary clutter and the potential for damage in the peripheral immune system. It is thought that thymocytes require TCR-mediated signals to prevent programmed cell death. Thymocytes with nonfunctional TCRs do not receive this survival signal and therefore undergo apoptosis within a limited time frame. DP thymocytes in the cortex that express a TCR of high avidity for self-peptide/MHC complexes undergo a process termed negative selection, in which

elimination occurs via activation-induced cell death. These apoptotic cells are rapidly engulfed by macrophages and cleared from the thymus in a highly efficient manner so that, despite the fact that > 90% of thymocytes die in the thymus, one must look very hard to detect dying cells. Finally, those DP thymocytes that express receptors with a moderate avidity for the self-MHC undergo positive selection and differentiate into SP thymocytes with upregulated levels of TCR. Those thymocytes that recognize MHC class I differentiate to become CD8 SP cells and those that recognize MHC class II differentiate into CD4 SP cells.

Production of Thymic Factors

In addition to the role that the thymus plays in T-cell differentiation and selection, the thymus also produces a myriad of factors that can act in either a localized or a secreted manner (Table 1). Much work has focused on the thymic hormones produced by thymic epithelial cells. These were initially characterized in crude thymic extracts and have subsequently been purified and characterized. The major peptides include thymopoetin, thymic humoral factor, thymosins, and thymulin, although many less well-characterized peptides exist. The functions of these peptides are related to the maturation of thymocytes as measured *in vitro* by phenotypic changes in bone marrow after coculture and/or related to the modulation of mature T-cell function as determined postinjection of the peptide. The majority of these peptides are detectable in the circulation, and levels are influenced by a variety of factors, including thyroid hormones, pituitary hormones, prolactin, growth hormone, and stress. Thymic humoral factor has been shown to enhance lymphocyte proliferation and IL-2 production *in vitro*. Thymopoetin binds cell surface receptors on immature thymocytes and mature T cells and appears to enhance early T-cell differentiation *in vitro*. The thymosins are actually a group of peptides, the most well characterized of which are thymosin $\alpha 1$ and thymosin $\beta 4$. Thymosin $\alpha 1$ induces the

expression of Thy-1, CD5, and CD8 on thymocytes and enhances mitogenic, cytokine, and antibody responses of lymphocytes *in vitro*. Both thymosin $\alpha 1$ and $\beta 4$ also increase terminal deoxynucleotidyltransferase (TdT) expression. However, of all the thymic factors, only the production of thymulin appears to be truly thymus restricted as evidenced by the observation that circulating thymulin levels decrease postthymectomy, whereas levels of the other thymic hormones are unaffected. Thymulin, which is only biologically active when complexed to zinc, is expressed by thymic epithelial cells and binds to receptors expressed on the surface of mature T cells, natural killer (NK) cells, and immature thymocytes. Functionally, thymulin can also induce expression of CD3 and CD8 on bone marrow cell and augment responses of mature T cells *in vitro*. However, while these thymic hormones can induce thymocyte changes *in vitro* or alterations in T cell function *in vivo*, a major issue that remains to be established is whether their *in vivo* function is primarily on tissues distant from the thymus or whether they also play a critical role in T-cell development *in vivo*.

While the thymic hormones are secreted and act on other target tissues, there are numerous thymic factors that most probably act strictly in a localized manner and are potentially involved in T-cell maturation (Table 1). Cytokines are produced primarily by the lymphocytes, dendritic cells, and macrophages of the thymus. Information obtained from mice in which expression of various of these cytokines and/or their receptors was eliminated by homologous recombination has contributed significantly to mapping their relative importance to T-cell differentiation and selection. For example, while the absence of IL-2 and IL-4 appears to have relatively little effect on T-cell differentiation, IL-7 is particularly critical to progression beyond the DN stage.

Expression of neuroendocrine hormones also occurs in the thymus in cells of both epithelial and bone marrow origin. Most notably, T cells synthesize corticotropin-releasing hormone (CRH) as well as proopiomelanocortin (POMC), the products of which include adrenocorticotrophic hormone (ACTH) and β -endorphin. Populations of thymic epithelial cells have been shown to express the steroidogenic enzymes, P450_{sc} and P450_{c11}, involved in synthesis of pregnenolone and corticosterone, respectively, and steroidogenesis occurs at levels sufficient to influence T-cell differentiation and selection. In the neuroendocrine system, CRH induces the secretion of ACTH that modulates glucocorticoid synthesis. While under normal circumstances, the production of these substances in the thymus does not occur at levels sufficient to significantly alter hypothalamic-pituitary-adrenal (HPA) axis

Table 1 Factors produced by the thymus

Thymic hormones	Cytokines	Neuroendocrine hormones
Thymopoetin	IL-1	ACTH
Thymosin $\alpha 1$	IL-2	CRH
Thymosin $\beta 4$	IL-4	GR
Thymic humoral factor	IL-6	PRL
Thymulin	IL-7	Somatostatin
	TNF α	Arginine vasopressin
	M-CSF	Corticosterone
	IFN- γ	

activity, it is interesting to speculate that the presence of these components within the thymus may lead to the paracrine regulation of localized glucocorticoid synthesis.

Glucocorticoids and Thymic Function

It has long been known that the culture of thymocytes with pharmacological levels of glucocorticoids can induce apoptosis, characterized by nuclear condensation, membrane blebbing, and DNA fragmentation. This sensitivity to glucocorticoids is the result of expression of the type II glucocorticoid receptor (GR). The GR has a 10-fold lower affinity for cortisol/corticosterone than the type I glucocorticoid receptor, also known as the mineralocorticoid receptor (MR), and is hence only activated in the presence of elevated levels of glucocorticoids. Cortical DP thymocytes are highly sensitive to exposure to glucocorticoids, whereas medullary thymocytes (CD4⁺ and CD8¹ SP) and cortical DN thymocytes are relatively resistant, despite expression of the GR in all of these populations. Alterations in sensitivity can be explained by concomitant changes in Bcl-2, a mitochondrial membrane protein that can rescue cells from apoptosis. Expression of Bcl-2 is high in DN thymocytes and decreases as cells differentiate to the DP stage. However, Bcl-2 levels increase postselection and are again high in SP thymocytes, the stage at which cells become relatively resistant to corticosteroids.

While the significance of GR expression in the thymus remains unclear, recent work has shed some light on this question. Enzymes responsible for glucocorticoid synthesis have been identified in thymic epithelial cells and have been shown to be active during the neonatal period when corticosteroid synthesis by the adrenals is low. Inhibition of glucocorticoid synthesis in fetal thymic organ cultures results in abnormal T-cell differentiation and selection. Similar findings were reported in genetically engineered mice in which GR expression had been significantly decreased due to expression of the antisense GR mRNA. Analysis of the thymus in these mice revealed decreased numbers of thymocytes and decreased viability of DP thymocytes in the absence of functional GR. These data suggest that physiological levels of locally produced glucocorticoids are critical for normal T-cell differentiation and selection.

Effects of Stress on the Thymus

Involution

Exposure of mammals to changes in physical, chemical, or emotional conditions results in the generation

of a “stress” response. Stress results in activation of the HPA axis, causing the release of CRH from the hypothalamus. CRH acts on the pituitary gland to facilitate synthesis and release of ACTH, which in turn induces the release of corticosterone from the adrenals. The elevation of corticosteroids in response to stress is rapid and dramatic. As discussed earlier, DP thymocytes are exquisitely sensitive to the elevation of glucocorticoids due to the expression of GR, therefore making the effects of stress on the thymus particularly evident. As early as the 1920s, Jaffe observed that the thymus involutes in response to stress and that adrenalectomy causes hypertrophy. This observation implicated adrenal products as responsible for the induction of thymic involution. However, while the correlation existed, it was not until significantly later that it was demonstrated that injection of corticosteroids mimicked stress-induced thymic involution by eliminating the majority of DP thymocytes. Furthermore, involution in stressed animals could be blocked by adrenalectomy or by treatment with the GR antagonist RU486.

Other Effects of Stress

While the most obvious effects of stress on the thymus is the dramatic decrease in size, attributable to the induction of apoptosis in DP thymocytes, glucocorticoids have a diverse range of effects other than induction of apoptosis. Elevated levels of glucocorticoids can suppress cytokines such as IL-1, IL-2, IL-3, IL-6, IL8, IL-12, G-CSF, GM-CSF, TNF- α , and IFN- γ and can induce the expression of various cytokine receptors. Some of these cytokines are expressed in the thymus and have been postulated to play roles in thymocyte differentiation. Glucocorticoid-induced downregulation of class II molecules on thymic antigen-presenting cells could prevent or hinder selection of CD4¹ class II-restricted T cells. Glucocorticoids released during stress are also well known to alter lymphocyte distribution, potentially due to alterations in the expression and/or affinity of adhesion molecules. Furthermore, exposure to glucocorticoids *in vitro* can induce the proliferation of thymic epithelial cells. All of these changes could significantly affect thymocyte function, namely the selection of the T-cell repertoire, during stress (Figure 2).

In addition to increased levels of glucocorticoids, stress-induced elevation of other hormones could also potentially affect thymic function. Stress results in increased levels of ACTH, growth hormone (GH), and prolactin (PRL), receptors for which are expressed in the thymus by either thymocytes or stromal elements. The importance of GH and PRL to normal thymic function is illustrated in two strains of hypopituitary

Figure 2 Schematic diagram of the effects of stress on the thymus. Stress results in activation of the HPA axis with release of CRH from the hypothalamus, thereby inducing the release of ACTH, GH, and PRL from the pituitary. The action of ACTH on the adrenals results in elevated levels of glucocorticoids that induce the death of DP thymocytes along with alterations in cell adhesion and MHC expression. Elevated ACTH, GH, and PRL can, among other potential effects, increase the production of thymulin, which can feedback on the pituitary and augment immune responses in the periphery.

mice (Snell-Bagg and Ames dwarf) that lack the acidophilic pituitary cells that secrete these hormones, resulting in small thymuses and few T cells in the periphery. These symptoms can be reversed to some degree by the transplantation of ectopic pituitary tissue. The impact of elevation of these hormones during stress has not yet been fully clarified. Both GH and PRL have been implicated independently in the promotion of thymocyte development and the augmented release of thymulin. The secretion of thymulin is also enhanced by ACTH. *In vivo* and *in vitro* studies of thymulin suggest that this peptide acts to enhance proliferation and cytokine secretion of T cells to antigen in the peripheral immune system. In addition, the secretion of thymulin may provide feedback to the HPA axis, acting on pituitary function (Figure 2). It has been shown that thymectomy results in degranulation of pituitary acidophilic cells, and implantation of neonatal thymic tissue can induce pituitary levels of luteinizing hormone and follicle-stimulating hormone.

Collectively, stress can induce multiple effects other than induction of thymocyte apoptosis. However, the contributions of many of these factors to stress-induced alterations in thymic function have been obscured by the overwhelming amount of thymocyte death during stress and have not yet been fully addressed. Stress-induced involution has been shown

to be reversible in that relief of the stress results in repopulation of the thymus in mice and rats. However, because of the complexities of the system, it is not understood if there are long-term effects of stress on the thymus. For instance, despite the fact that MHC class II levels recover to normal levels post-stress, what effect does glucocorticoid-induced down-regulation of MHC class II or alteration in cytokine production and/or responsiveness during stress have on the selection of surviving thymocytes prior to recovery? Skewed selection of the repertoire would have a lasting impact on antigen responsiveness in the peripheral immune system. Nor is the functional significance of stress-induced thymic involution understood. One might speculate that in times of stress, the protection of immune status is critical and elimination of huge numbers of T-cell precursors seems, at best, counterintuitive. However, stress comes under many guises, one of which is infection by pathogens. At times in which foreign antigen is present at sufficiently high concentrations that may reach the thymus, it would be prudent to restrict thymocyte selection to avoid inadvertent tolerance induction to pathogens. One might argue further that since high levels of glucocorticoids can alter MHC class II levels and cell adhesion, selection in the thymus would be skewed compared to that which would occur during an unstressed state. Perhaps the induction of cell death in those cells actually undergoing selection, the DP cells, is the best way to prevent this potential skewing. However, this is speculation at best, and a great deal of work in this field remains before the impact of stress on the thymus and its products is fully understood.

Regulation of Thyroid Hormone Bioactivity
Effects of Stress/Glucocorticoids on Central Regulation of Thyroid Function
Effects of Stress/Glucocorticoids on Thyroid Hormone Metabolism
Conclusion

Glossary

<i>Arcuate nucleus</i>	Hypothalamic nucleus involved in the regulation of appetite and food intake, with important projections to the paraventricular nucleus.
<i>Cytokines</i>	Mediators in the response of the immune and endocrine systems to inflammation.
<i>Deiodination</i>	An enzymatic reaction by which iodine is removed from the thyroid hormone, resulting in the activation or inactivation of the hormone.
<i>Glucocorticoids</i>	Hormones from the adrenal cortex (cortisol in humans) involved in the regulation of glucose metabolism; their secretion induced by stress.
<i>Low T₃ syndrome</i>	The decrease in plasma bioactive thyroid hormone during nonthyroidal illness and other stress conditions.
<i>Nonthyroidal illness (NTI)</i>	An illness not primarily affecting the thyroid gland that is associated with a decrease in plasma bioactive thyroid hormone.

Paraventricular nucleus (PVN) An important hypothalamic nucleus for the production of hypophysiotrophic factors.

In this article, stress is used simplistically as a general term for pathophysiological conditions associated with a stimulation of the hypothalamus-pituitary-adrenal (HPA) axis that are not caused by pathological abnormalities in the HPA axis itself. These stress conditions include those inflicted by disease, inflammation, injury, surgical trauma, fasting, heat and cold exposure, and emotional stress. In addition to stimulating of the HPA axis, these conditions are often associated with profound alterations in several thyroid-related parameters, which are commonly referred to as the low T₃ syndrome. Stress-induced alterations in thyroid hormone bioactivity result to an important extent from the centrally mediated suppression of thyroid function and the inhibition of the peripheral conversion of the prohormone thyroxine (T₄) to the active hormone triiodothyronine (T₃). Both central and peripheral effects may be mediated in part by the high cortisol levels. This article first gives a brief introduction to the regulation of thyroid hormone levels and bioactivity. Subsequently, it describes in some detail the stress-induced changes in thyroid hormone regulation at the central and peripheral levels and speculates about the role of increased cortisol levels in these changes.

Regulation of Thyroid Hormone Bioactivity

Normally, thyroid function is predominantly controlled by thyroid stimulating hormone (TSH), secreted by the pituitary. In turn, the TSH-producing cells of the pituitary are regulated by various hypothalamic factors, most significantly, in a positive manner, by thyrotropin releasing hormone (TRH) and, in a negative way, by somatostatin and dopamine. TSH

synthesis and release are also controlled by peripheral factors, notably by negative feedback regulation by thyroid hormone and by the inhibitory effect exerted by cortisol (Figure 1).

TRH is a tripeptide with the structure pGlu-His-Pro-NH₂ (where pGlu is pyroglutamic acid), which is produced not only in the hypothalamus but also throughout and even outside the central nervous system (e.g., in the pancreas). It is generated from a precursor protein, which in humans consists of 242 amino acids, including six TRH progenitor sequences Baa-Baa-Gln-His-Pro-Gly-Baa-Baa (where Baa is basic amino acid Arg or Lys). Enzymatic cleavage at Baa residues and further processing of the Gln-His-Pro-Gly intermediate by N-terminal cyclization and C-terminal amidation result in the generation of mature TRH.

Figure 1 Stimulation of the hypothalamus-pituitary-adrenal axis by stress, the importance of cortisol in mediating the suppression of the hypothalamus-pituitary-thyroid axis, and the inhibition of peripheral T₄ to T₃ conversion. ACTH, adrenocorticotrophic hormone; CRH, corticotropin releasing hormone; T₃, triiodothyronine; T₄, thyroxine; TRH, thyrotropin releasing hormone; TSH, thyroid stimulating hormone.

Hypothalamic TRH stimulates not only TSH but also prolactin and, in some conditions, growth hormone secretion from the anterior pituitary by acting on a common (type I) TRH receptor expressed by thyrotrophs, lactotrophs, and somatotrophs. Another (type II) TRH receptor has been characterized in the brain. TSH is an ~30-kDa glycoprotein consisting of an α subunit of 92 and a β subunit of 118 amino acids. The α subunit is identical to that of luteinizing hormone and follicle-stimulating hormone, whereas the β subunit conveys hormone specificity.

TSH stimulates the production and secretion of thyroid hormone from the thyroid gland. Under normal conditions, including an adequate iodine intake, the adult human thyroid gland largely produces T₄ (3,3',5,5'-tetraiodothyronine), which has little intrinsic bioactivity and is generally regarded as a precursor of the bioactive form of T₃ (3,3',5-triiodothyronine). Most T₃ is produced by the outer-ring deiodination (ORD) of T₄ in peripheral tissues. Both T₄ and T₃ are inactivated by inner-ring deiodination (IRD) to 3,3',5'-triiodothyronine (rT₃) and 3,3'-diiodothyronine, respectively. Three iodothyronine deiodinases are involved in these processes. The type I deiodinase (D1) is located in the liver, kidney, and thyroid and, surprisingly, has both ORD and IRD activities. Nevertheless, the enzyme in liver, in particular, is thought to be the main site for the peripheral production of T₃ from T₄. The type II deiodinase is expressed in the brain, the pituitary, and, perhaps also to significant extents, the human heart and skeletal muscle. It has only ORD activity and is thought to be important for the local production of T₃ in tissues such as the brain, although the enzyme in the skeletal muscle may contribute to plasma T₃ production. Finally, type III deiodinase (D3) is found in the brain, skin, placenta, pregnant uterus, and various fetal tissues. It has only IRD activity and thus catalyzes the production of rT₃ from T₄ as well as the degradation of T₃. Thus, two deiodinases (D1 and D2) are capable of thyroid hormone activation and two enzymes (D1 and D3) are capable of thyroid hormone inactivation. The relative activities of these deiodinases thus have a major impact on thyroid hormone bioavailability. The deiodinases are homologous selenoproteins, featuring essential selenocysteine residues in their catalytic centers. It is remarkable therefore that both the synthesis and the metabolism of thyroid hormone are dependent on the trace elements iodine and selenium.

The regulation of the bioactivity of thyroid hormone does not depend only on the activities of the different deiodinases; iodothyronines are also inactivated by the conjugation of the phenolic hydroxyl group with glucuronic acid or sulfate. All the enzymes

involved are located intracellularly, as are the receptors mediating the biological effects of T_3 , which are located in the nucleus. Therefore, the metabolism and action of thyroid hormone in the different tissues require the uptake of T_4 and T_3 across the cell membrane. There is much evidence suggesting that the downregulation of the conversion of peripheral T_4 to T_3 during stress may be brought about by the decreased uptake and/or conversion of T_4 in T_3 -producing tissues such as the liver. Because this results in decreased T_3 action and, thus, lower energy expenditure and protein catabolism, this is supposed to be a beneficial adaptation mechanism to sustain the stressful conditions.

Effects of Stress/Glucocorticoids on Central Regulation of Thyroid Function

Hypothalamic Thyrotropin Releasing Hormone

The important physiological role of hypothalamic TRH in the regulation of the pituitary-thyroid axis is clearly established. Immunocytochemical studies in the 1970s and 1980s demonstrated the presence of many (pro-)TRH-containing neurons in the PVN of the rat hypothalamus; in the 1990s the distribution of TRH cells in the human hypothalamus was reported. Although TRH-containing neurons occur in many hypothalamic and extrahypothalamic areas, TRH cells in the PVN appear to be selectively involved in the regulation of the pituitary-thyroid axis. This was first suggested by immunocytochemical studies in hypothyroid rats showing changes in TRH cells mainly in the parvocellular portion of the PVN. The assumption was confirmed by subsequent studies on TRH mRNA in the PVN of hypothyroid rats and by studies involving the endocrine effects of PVN lesions. Thus, TRH cells in the PVN are important for the set-point regulation of serum thyroid hormones, and circadian and circannual variations in TRH content, as observed in the rat PVN, may explain circadian and seasonal variations in serum concentrations of TSH.

Thyroid hormone feedback regulation is probably mediated by the thyroid hormone receptor (TR), which is expressed by TRH neurons in the PVN and by cells in the arcuate nucleus (ARC). The ARC is also one of the major hypothalamic sites expressing D2, which converts the prohormone T_4 into bioactive T_3 . Studies suggest that neuropeptide Y (NPY) cells from the ARC innervate TRH cells in the PVN that project to the median eminence. Therefore, the ARC appears to be one of the pivotal loci for thyroid hormone feedback regulation in the central nervous system.

Stress, Glucocorticoids, and the Central Component of the Hypothalamic-Pituitary-Thyroid Axis

Different types of stress may induce differential changes in the central component of the hypothalamic-pituitary-thyroid (HPT) axis. For example, cold exposure in rats increases TRH mRNA in the PVN, as shown by *in situ* hybridization, and leads to increased serum concentrations of TSH. In contrast, food deprivation in rats decreases TRH mRNA in the PVN and *in vitro* TRH release and is associated with lower serum concentrations of thyroid hormones. In humans, severe illness in the absence of overt thyroid disease, NTI, is associated with a decrease in serum T_3 . Despite low serum concentrations of thyroid hormones, serum TSH in NTI is typically normal or reduced. These observations point to a change in hypothalamic thyroid hormone feedback regulation. In line with this notion are profound alterations in the circadian TSH rhythm and decreased TRH mRNA expression in the PVN of patients with NTI.

Various studies have suggested a role for glucocorticoids in the alterations of the central component of the HPT axis during stress. For example, glucocorticoid excess suppresses TSH in patients and also in animal experiments. Conversely, glucocorticoid deficiency is associated with mild elevations in serum TSH, pointing to a role for glucocorticoids in the regulation of TSH release. The demonstration of glucocorticoid receptor (GR) expression by TRH cells in the rat PVN and the presence of a glucocorticoid response element in the TRH gene suggest that the inhibitory effect of glucocorticoids on TSH secretion involves the inhibition of TRH synthesis in the PVN. This suggestion was confirmed by elegant studies involving the concomitant determination of TRH mRNA and corticotropin releasing hormone (CRH) mRNA in the PVN of rats after bilateral adrenalectomy with or without subsequent treatment with glucocorticoids. After adrenalectomy, there was an expected rise in CRH mRNA, but also of TRH mRNA in the PVN. After corticosterone or dexamethasone administration, both CRH and TRH mRNA showed a major reduction. Therefore, glucocorticoids appear to inhibit TRH cells in the rat PVN, possibly directly via GR expressed by these cells. This may explain why acute bolus injections of dexamethasone suppress basal TSH release, whereas the TSH response to TRH remains intact. After long-term pharmacological glucocorticoid excess, the TSH response to TRH is also blunted. Some, but not all, studies in patients with endogenous hypercortisolism have reported an inverse correlation between parameters of cortisol excess and the TSH response to TRH, suggesting an inhibitory effect of glucocorticoids at the pituitary level (Figure 1).

Complex interactions of glucocorticoids and TRH cells have been reported in *in vitro* systems. The short-term administration of dexamethasone to dispersed hypothalamic cells showed concentration-dependent biphasic effects of dexamethasone on TRH mRNA and TRH cell content. In addition, dexamethasone stimulates TRH and TRH mRNA expression in fetal rat diencephalic neuronal cultures. In contrast to the *in vivo* situation, TRH is expressed by anterior pituitary cells in culture, which is increased further by dexamethasone. The discrepancy between the negative effects of dexamethasone *in vivo* and its positive effects *in vitro* on TRH expression in hypothalamic cells may be explained by the nonphysiological culture conditions and/or the disruption of inhibitory innervation of TRH cells in the PVN. In cultured human placental cells, cortisol at concentrations of 10–100 nmol l⁻¹ inhibits D2 activity. Severe illness is associated with increased serum concentrations of cortisol. In line with decreased D2 activity in the hypothalamus of patients with severe illness is the observation that the hypothalamic concentration of T₃ (but not of T₄) is decreased markedly in postmortem tissue compared with patients with acute traumatic death. Therefore, we may speculate that the hypercortisolism of severe disease is one of the factors leading to a decreased expression of TRH in the PVN, thereby contributing to the persistence of low serum TSH (Figure 1). In addition, the bioavailability of T₃ may be reduced by the decreased activity of D2. In contrast, hypothalamic expression of D2 is increased in rats during starvation, again pointing to the differential effects of stress on the central component of the HPT axis according to the type of stress.

Effects of Stress/Glucocorticoids on Thyroid Hormone Metabolism

Pathophysiology of Peripheral Thyroid Hormone Metabolism

As mentioned earlier, stress conditions such as fasting, illness, and injury are associated with major changes in plasma thyroid hormone levels. Marked decreases in plasma T₃ and increases in plasma rT₃ are observed consistently in these conditions, and plasma T₄ and free thyroxine (FT₄) levels may also be affected in critical illness. In general, the magnitudes of the decrease in plasma T₃ and of the increase in plasma rT₃ are correlated with objective measures of the severity of the disease, such as loss of organ function and fever. It has been suggested that the plasma T₃/rT₃ ratio is a good indicator of the clinical condition of the patient. However, it should be mentioned that the increase in plasma rT₃ is not found in

all diseases; notable exceptions are acquired immunodeficiency syndrome (AIDS) and renal disease. Initially, the stress-induced changes in plasma T₃ and rT₃ were interpreted as reflecting a shift in the peripheral metabolism of the prohormone T₄, that is, to less conversion by ORD to active T₃ and more conversion by IRD to inactive rT₃. Kinetic analysis of T₃ and rT₃ turnover during fasting and illness has confirmed that the decrease in plasma T₃ is due to a decrease in plasma T₃ production with little or no change in plasma T₃ clearance. However, the increase in plasma rT₃ seen in fasting or sick subjects appears to be caused by a decrease in plasma rT₃ clearance rather than an increase in plasma rT₃ production.

Because D1 in the liver is supposed to be an important site for the production of T₃ and the degradation of plasma rT₃, the decrease in plasma T₃ and increase in plasma rT₃ in the low T₃ syndrome may be caused by diminished hepatic D1 activity. Evidence suggests that a decrease in the hepatic content of reduced glutathione (GSH) may contribute to a decrease in D1 activity during fasting because GSH is the most abundant intracellular thiol compound and the activity of D1 is dependent on thiol cofactors. The stress-induced decrease in hepatic D1 activity may also be caused by a decrease in the expression of the enzyme at the transcriptional or posttranscriptional level. In this respect, studies of the effects of fasting on hepatic D1 expression in rats have produced confusing results. This is because fasting in rats is associated with a rapid and marked downregulation of TSH secretion, which results within 2 days in decreases in plasma T₄ and T₃ to hypothyroid levels. Strange enough, D1 gene expression is under the positive control of its own product T₃. Therefore, fasting in rats induces a hypothyroid state, which leads to a decrease in D1 expression. If plasma thyroid hormone levels in fasted rats are kept normal by T₄ replacement therapy, the decrease in hepatic D1 expression is largely prevented.

Even before D1 was identified as a selenoprotein, it was demonstrated that hepatic and renal D1 activities are strongly decreased in rats fed a selenium-deficient diet. It has subsequently been shown that a severely deficient selenium intake in humans may result in modest changes in plasma T₄, T₃, and rT₃ levels compatible with minor decreases in tissue D1 activities. Although selenium stores may diminish under certain clinical conditions, such as long-term parenteral nutrition, it is unlikely that this contributes significantly to the generation of the low T₃ syndrome. Thus, there is little solid evidence to support the hypothesis that the decrease in plasma T₃ and the increase in plasma rT₃ during fasting or other stress conditions are caused by a decreased hepatic D1 activity.

Kinetic modeling of the plasma disappearance of injected radioactive T_4 , T_3 , and rT_3 suggests that the fractional transfer rates of T_4 and rT_3 , more than that of T_3 , from plasma to the rapidly equilibrating tissue pools are decreased during fasting and illness. This is consistent with a decreased uptake of T_4 and rT_3 in the liver and, hence, a decreased intracellular availability of these substrates for conversion by D1. Studies of the uptake of different iodothyronines by isolated rat and human hepatocytes and in the isolated perfused rat liver have provided possible clues for the mechanism of these changes. These studies have produced strong evidence that the uptake of the different iodothyronines by liver cells does not occur by simple diffusion of these lipophilic compounds through the lipid bilayer of the cell membrane but is mediated by transporters that are at least partially ATP and Na^+ dependent. Competition experiments and ATP-depletion studies have suggested that uptake of T_4 and rT_3 and the uptake of T_3 by hepatocytes are mediated by different transporters, where the former is more sensitive to decreases in cellular ATP content than the latter.

The stress-induced decrease in plasma T_3 and increase in plasma rT_3 can thus be explained by a decreased activity of a hepatic T_4/rT_3 transporter with little change in the activity of the T_3 transporter. This could be the result of a decrease in cellular ATP content during fasting and illness, which would cause a much greater inhibition of hepatic uptake of T_4 and rT_3 than of T_3 . Although hepatocyte incubation studies have indicated that relatively small decreases in cellular ATP suffice to cause significant inhibition of T_4/rT_3 uptake, it remains to be established whether similar diminutions in tissue ATP content may occur under pathophysiological conditions *in vivo*. Increased plasma concentrations of inhibitors are perhaps a more likely mechanism for the decreased hepatic uptake of T_4 and rT_3 during fasting and illness. Again, studies using isolated hepatocytes have provided support for this hypothesis, in that they have shown significant inhibition of T_4 uptake by various compounds, the plasma levels of which are elevated during fasting and illness (fatty acids) or specifically in liver disease (bilirubin) or kidney failure (3-carboxy-4-methyl-5-propyl-2-furan propanoic acid, CMPF; and indoxyl sulfate). The clinical relevance of these data is strongly supported by findings that in the presence of serum from patients with NTI, the uptake and metabolism of T_4 by hepatocytes are diminished compared with incubations containing serum from healthy subjects. Furthermore, the inhibition of T_4 uptake and metabolism by NTI serum are strongly correlated with the severity of the disease. Therefore, the decreased hepatic uptake of T_4 and rT_3 appears to be an important

mechanism for the decreased T_3 production and rT_3 clearance during fasting and illness.

Possible Role of Glucocorticoids in the Generation of Low T_3 Syndrome

Most, if not all, conditions characterized by the low T_3 syndrome are also associated with the stimulation of the HPA axis (Figure 1). In inflammatory conditions, this is mediated by the induction of a cascade of cytokines, including tumor necrosis factor (TNF)- α , interleukin (IL)-1, and IL-6. The administration of TNF- α or IL-6 to human subjects results in a decrease in plasma T_3 and in an increase in plasma rT_3 . Although these findings may reflect the indirect effects of these cytokines because their administration also induces NTI, evidence shows that IL-6 is an important mediator for the alterations in thyroid hormone metabolism. Plasma IL-6 levels generally correlate well with disease severity. Furthermore, a strong negative correlation has been observed between plasma IL-6 and T_3 levels in a number of studies in NTI patients. This correlation is improved by including the concentrations of soluble cytokine receptors.

The involvement of the cytokine network in the generation of low T_3 syndrome has also been addressed in multiple studies testing the effects of the administration of different cytokines on various thyroid parameters in rats or mice. The results of these studies have been difficult to interpret because rodents do not appear to be good models for investigation of the mechanisms by which the low T_3 syndrome is generated in humans. As mentioned earlier, the central suppression of thyroid function induced by stress is much more pronounced in rats than in humans. Moreover, transthyretin (TTR) is the main plasma thyroid hormone-binding protein in rodents, in contrast to humans in which thyroxine-binding globulin (TBG) is the major carrier. TTR is a negative acute-phase reactant; that is, its plasma concentrations fall markedly during illness, resulting in much stronger decreases in plasma T_4 -binding capacity in rats than in humans. However, evidence for a possible role of IL-6 in mediating the inhibition of peripheral T_3 production during illness was obtained in mice. In different NTI models, the decrease in plasma T_3 was somewhat less in IL-6 knockout mice than in wild-type controls, whereas no effect of IL-6 deletion was seen on the decrease in plasma T_4 .

Two lines of evidence strongly support an important role for glucocorticoids in the generation of the low T_3 syndrome. First, the administration of glucocorticoids such as dexamethasone and prednisone to human subjects not only inhibits TSH secretion (see earlier discussion) but also results in acute and marked decreases in plasma T_3 and increases in

plasma rT_3 levels, whereas plasma T_4 levels show little change. Second, all stress conditions associated with the low T_3 syndrome are also accompanied by large increases in plasma cortisol levels. In many, but not all, clinical studies of NTI, a strong negative correlation has been observed between plasma T_3 and cortisol levels. That such a correlation has not been found in all studies may be explained by temporal differences in the responses of plasma cortisol and T_3 to stress, with increases in cortisol preceding decreases in T_3 if they are causally related. However, a serious argument against such a causal relationship has been put forward by studies examining changes in plasma hormone levels in patients undergoing surgery under general anesthesia without or with additional epidural anesthesia. Although the surgery-induced increase in plasma cortisol is strongly diminished, but not prevented, by epidural anesthesia, the decrease in plasma T_3 and the increase in rT_3 are not affected. Although these data do not support the hypothesis that cortisol is an important mediator in the generation of the low T_3 syndrome by surgical stress, they do not exclude the possibility that the smaller increase in plasma cortisol under epidural anesthesia is still sufficient to interfere, perhaps in concert with other factors, with the peripheral metabolism of thyroid hormone.

A particularly interesting study in this respect has been conducted in rats, in which the effects of immobilization stress on plasma thyroid hormone levels were examined. This was associated with a 30-fold increase in plasma corticosterone, an $\sim 40\%$ decrease in plasma T_3 , and an $\sim 75\%$ increase in plasma rT_3 , as well as marked decreases in hepatic and renal D1 activities. These stress-induced changes were not seen in animals that had been surgically or chemically adrenalectomized and treated with replacement doses of corticosterone. The mechanism by which glucocorticoids affect peripheral thyroid hormone metabolism has not been established. Evidence suggests that both the uptake of thyroid hormone and D1 expression may be inhibited in the liver and kidney *in vivo*. However, *in vitro* dexamethasone has been shown to stimulate the expression of the D1 and D2 genes in various cell cultures (e.g., trophoblasts, neurons, glia cells, and hepatoma cells), perhaps by stimulating the differentiation of these cells. The physiological relevance of these observations, however, is uncertain.

It should be realized that the low T_3 syndrome may result not only from a decreased production of T_3 and clearance of rT_3 but also from an increased clearance of rT_3 and production of rT_3 . It has been reported that the administration of dexamethasone to human subjects increases plasma rT_3 production, whereas plasma rT_3 clearance is not changed. Finally,

it should be realized that the effects of glucocorticoids on thyroid hormone metabolism depend strongly on the stage of development. In the fetal circulation, T_3 levels are low and rT_3 levels are high. Although low expression of D1 in liver and kidney may contribute to low T_3 syndrome, the major cause is probably the high expression of D3 in the placenta, uterus, and various fetal tissues. Studies in chickens have indicated that the high D3 expression in the embryonic liver is acutely downregulated by glucocorticoids, resulting in a dramatic increase in plasma T_3 . Thus, there are multiple, sometimes opposite, interactions between glucocorticoids and peripheral thyroid hormone metabolism.

Conclusion

We have discussed the decrease in TSH secretion and peripheral T_4 to T_3 conversion (low T_3 syndrome), which occur in various forms of stress. This is believed to be a beneficial defense mechanism, which saves energy and minimizes catabolism. All these conditions are also associated with a stimulation of the pituitary-adrenal axis. Together with findings that the effects of stress on plasma TSH and thyroid hormone levels are mimicked by the administration of glucocorticoids, this suggests that cortisol is an important mediator in the generation of the low T_3 syndrome during stress at both central and peripheral levels. However, studies of the effects of epidural anesthesia, which decreases the response of cortisol but not those of T_3 and rT_3 to surgical stress, suggest that there is not always a causal relationship between stress-induced changes in plasma cortisol and thyroid hormone levels.

UN
Convention against Torture and Cruel, Inhuman or Degrading Treatment or Punishment
UN Vienna Declaration

employer-committed harassment opposed by governmental laws.

A group founded in 1985 in Copenhagen to disseminate information about torture, its consequences, and the possibility of preventing torture. The IRCT also promotes education and training and raises international funds for the IRCT network, consisting of 98 accredited and globally distributed rehabilitation centers for victims of torture.

Established in 1982, a center in Copenhagen that examines and documents torture and develops diagnostics and treatment of torture victims through research.

Convention (1984), with 33 articles, that defines governmental and political torture in article 1.

Declaration (1993) that refers in chapter 5 to torture as “one of the most atrocious

World Medical
Association's
Tokyo
Declaration

violations against human dignity" and "urges all states to put an immediate end to the practice of torture ... and abrogate legislation leading to impunity for torture."

Declaration (1975) stating that "Torture is defined as the deliberate, systematic or wanton infliction of physical or mental suffering by one or more persons acting alone or on the orders of any authority, to force another person to yield information, to make a confession, or for any other reason."

Torture in the World Today

The definition of torture executed by states or state-connected institutions used in this article is that expressed by the United Nations (UN) Torture Convention, adopted in 1984 and entered into force in 1987. This convention states that torture is present when (1) severe pain or suffering, whether physical or mental, (2) is intentionally inflicted on a person (3) for such purposes as obtaining from him or her or a third person information or a confession ..., (4) at the instigation of or with the consent or acquiescence of a public official or other person acting in a official capacity. The World Health Organization (WHO) introduced in 1986 the concept of organized violence, including "torture, cruel, inhuman or degrading treatment or punishment" as in article 5 of the UN's Universal Declaration of Human Rights (1948).

Imprisonments without trial, mock executions, hostage taking, or any other form of violent deprivation of liberty fall under the category of organized violence.

Democracy and Torture

Article 8 of the Vienna Declaration states that "Democracy, development and respect for human rights and fundamental freedoms are interdependent and mutually reinforcing." From this statement, it could be concluded that a necessity for development is democracy based on the respect for human rights.

In other words, there exists a close correlation between democracy and torture. The more democracy in a given country, the less torture is carried out. The more torture, the less democracy, *inter alia*, as it appears from Amnesty International's regular annual reports.

Torture works against democracy. Torture can even be said to be a very strong tool against democracy, since torture goes against the concepts of democracy, freedom of speech and expression, and the right to political dissent. One purpose of torture is to silence

the tortured and those who think alike. A result of this is that people living under pressure and lawless conditions, and consequently with prospects of violations and torture, more or less constantly find themselves in stressful situations.

Those tortured can be identified as ethnic groups and parts of a population, as individuals as well as groups, and as men and women who hold leadership positions and make a stand for democracy in authoritarian regimes. The latter may be politicians in opposition, student leaders, journalists, leaders of ethnic minorities, union members, or human rights defenders.

The Magnitude of the Problem

Torture ranks as one of the most profound human rights abuses, and the magnitude of this worldwide problem is immense. Torture as well as awareness of torture have increased. Government-sanctioned torture exists in more than 40 UN member states and is carried out sporadically in many more. A worldwide survey by Amnesty International (AI) showed that 150 countries, out of 195 investigated, practiced torture. It is also known from AI's yearly reports that torture may occur sporadically in prisons and by the police, even in civilized and democratic societies. Recently, solid evidence that torture exists even in democratic states has been demonstrated by U.S. military personnel torturing prisoners in the Abu Ghraib prison in Iraq in 2004 as well as by information of abuses and alleged torture by coalition forces in Iraq.

There is not a good methodology to calculate the magnitude of the problem of torture worldwide. The number of torture survivors is probably approximately several million.

Every year, torture forces many thousands to flee from their home country. Globally, there are more than 14.5 million refugees, and an additional 19 million have been internally displaced in their home country. A large number of these people have been tortured, although an exact figure does not exist. Community samples are rare. Jaranson and co-workers found in 2004 prevalence rates of torture ranging from 25 to 69% among selected East African communities in Minnesota. Victims of torture often do not want to report on or tell about their traumatic past, either because of fear of retaliation or persecution or because of the deep feelings of shame that are a result of the torture.

Types of Torture

The torture process typically starts with the arrest of the victim, usually at night, with a formidable display

of power and unnecessary use of violence. The softening phase, which often follows, usually consists of a couple of days and nights of unsystematic violence with beating, kicking, and other humiliations. After this, systematic torture starts when the torturers explore the weak spots of the victim to make him or her break down. The aim is to not break down the victim too quickly.

Systematic torture can be conducted in both physical and psychological forms, usually performed at the same time, which aim for a long-lasting destruction of the physical and psychological well-being of the victim. Sophisticated torture methods can cause destruction of the identity and self-respect of human beings while allowing the perpetrators to claim that the victims were never exposed to torture. A new science has developed, and modern day torture is practiced in many countries with the assistance of medical doctors and psychologists.

Physical Torture

The following is a summary of physical torture methods. Electric shocks are applied to the most sensitive areas of the body, or the victim is suspended for hours by his or her arms or by a leg. The head can be forced under water until the victim is about to suffocate, or the skin is burned by cigarettes or red-hot iron rods. The victims are beaten systematically, typically under the feet until the soles are badly damaged. Sexual offenses are common. Women in particular are attacked as sexual objects, and men are harmed in their ability to function as men. Trained dogs can be used for direct attacks or for rape of both men and women. Mock executions bring the individual to a loss of reality and a nightmarish state of almost suspended animation. The situation during the victim's detention is further worsened by filthy food and drinking water. Freedom of movement is limited, and prisoners are closely packed in small cells and thus forced to take turns sleeping. Sanitary conditions are extremely poor, and any request for visiting the toilet will often be turned into a pretext for torture.

Psychological Torture

Psychological torture takes place at the same time as physical torture: for instance, deprivation of sleep, blindfolding, and lack of human contact are forms of psychological torture. These methods leave the victim with a deep sense of helplessness, fear, and extreme stress and may cause hallucinations. The victim can be totally isolated for months or years, and during that time the victim does not know what is going to happen. The victim's family will often have no knowledge of his or her whereabouts. Psychological

methods of great social and psychological impact are sexual torture and situations in which victims are forced to be present during torture to others, particularly relatives and children.

Many victims are threatened with having to do or say things that go against their ideology or religious convictions, with purpose of attacking fundamental parts of their identity, such as self-respect and self-esteem. The victims' political and ethical values are particularly attacked by the torturers when they, e.g., force the victims to sing songs that praise everything they fought against.

The attempt to break down the victims' personality often begins at the time of arrest, with the removal of personal belongings, including life-saving drugs and glasses, and replacing them with badly fitting uniforms. Names are replaced with numbers, and victims are instructed to address their jailers with great respect.

It is important to understand that the nature of torture influences even common life situations. During torture, the perpetrators often avail themselves of common objects used by everyone, such as cigarettes, telephone books, knives, needles, water, light, and noise (often the radio is tuned to music), and as a result, the survivors will in the future associate torture with these everyday objects. In such a manner the trauma of torture is specific. The survivor of torture will be reminded of his or her torture on the conscious as well as the unconscious level nearly constantly throughout the day, year in and year out. And this is what the torturer intends: that the recollection of the torture, the reminders should nag and plague the survivor for a long time or even the rest of his or her life. In the treatment process this is counteracted by psychotherapy, among other options.

Delimitation

History

The recognition of symptomatology related to torture was a phenomenon of the 1970s. At that time, there was no systematic medical literature on torture. Subsequently, a series of findings was encountered that were contrary to expectations.

The first detailed, systematic studies of the methods of torture and its immediate aftereffects were presented by Danish medical doctors in 1974–75. The search for forensic medical evidence that torture had occurred had begun. At an early stage, it was concluded that the worst sequelae of torture were psychological. That was the first surprise, confirmed by other international studies: not only is torture

unbearable and extremely painful, but it also stays with survivors and haunts them many years later.

Diagnosing Government-Sanctioned Torture

Physicians have learned much about the documentation of torture based on both physical and psychological sequelae. Examination methods, interview techniques, and data collection have become more sophisticated. Through medical examination, physicians can now detect indications of torture in most of the major organ systems, including the dermatological, cardiopulmonary, gastrointestinal, musculoskeletal, neurological, urological, gynecological, otorhinolaryngological, and ophthalmological systems, as well as in the teeth. Psychological symptoms now fit into the well-defined category of posttraumatic stress disorder (PTSD) as defined by the WHO and the American Psychiatric Association in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV). The medical profession's level of sophistication in assessing torture victims has evolved to the extent that the concept of a torture syndrome based on the results of both physical and mental torture has been proposed.

Symptoms and Aftereffects

The Effect of Torture

The mental health consequences of torture are usually more persistent and protracted than the physical aftereffects, although there is considerable overlap of the physical and psychiatric effects. Torturers today are capable of creating conditions that effectively break down the victim's personality and identity and his or her ability to live a full life with other human beings. Deep feelings of guilt and shame often occur after torture.

Feelings of guilt may be caused by the mere fact having survived when friends died while being tortured, or perhaps by having given information that could have harmed friends. Guilt may also be produced by the so-called impossible choice, when victims are forced to choose between, for instance, revealing the names of their friends and seeing members of their family tortured. Regardless of what the victim chooses, the end result is a disaster for which the victim feels responsible. And that is exactly the aim of torture as it is practiced in this day and age.

Psychological studies of survivors of torture at the Rehabilitation and Research Centre for Torture Victims (RCT) have revealed the following symptoms: anxiety, memory gaps, depression, changed personality, frequent nightmares about prison and torture, and difficulty in remembering and concentrating. Fatigue,

headache, and sexual disturbances are also common. These reactions may in many situations be considered normal in ordinary people who have been exposed to something as perverse, cruel, and abnormal as torture. In situations with beatings, studies have suggested an association between head trauma and neuropsychiatric symptoms that could be recognized as cognitive deficits.

The psychological aftereffects of torture can be considered to be the same in all torture survivors, whereas the physical aftereffects of torture depend upon the type of physical torture methods used. Falanga (persistent beatings on the soles of the feet) results in impaired walking, suspension by the arms results in shoulder pain, and so on.

Over the years the examinations of many hundreds of survivors from approximately 100 countries have provided knowledge about the methods of torture and their aftereffects. These studies have made it possible to ascertain that the methods of torture used are the same all over the world. This is a natural consequence of the fact that the aim of torture is the same all over the world: to break down strong persons' identities. The methods are the same, and so are the aftereffects. This knowledge, which is most useful in medical work on torture, was obtained through systematic analysis.

Posttraumatic Stress Disorder in Torture Survivors

Neuropsychiatric symptoms are often difficult to correctly diagnose. The multiplicity of symptoms is great and comorbidity occurs. Psychiatric disorders such as major depression and PTSD are frequently seen in torture survivors. At the Centre for Victims of Torture in Minnesota, nearly 70% of the clients meet diagnostic criteria for PTSD, with nearly all of the clients exhibiting at least one or two symptoms of this disorder. Mollica and Caspi-Yavin then concluded that "the attempts to describe a single 'torture syndrome' ... are generally unconvincing." Finally, they, who have considerable experience working with refugee survivors from southeast Asia, concluded that "medical investigations of torture survivors not only failed to demonstrate a unique torture syndrome, but demonstrated symptoms closely associated with the DSM-III-R diagnosis of PTSD." Consequently, investigators have shifted their focus away from demonstrating the presence of a unique syndrome to establishing the prevalence of PTSD in torture survivors.

However, the association between PTSD and torture is not a simple linear one. Research has shown that although there is an association between torture

and PTSD, different forms of torture produce different PTSD symptoms. More specifically, individuals who experienced isolation or blindfolding, impact torture, and other types of physical torture had a predominance of PTSD intrusion symptoms, whereas individuals who had been sexually tortured described more avoidance phenomena. This may suggest that PTSD in the cases of tortured individuals is not a uniform syndrome.

It should be kept in mind that controversy exists about the applicability of diagnosing PTSD in torture survivors. In countries where torture is routinely practiced, PTSD often is considered as Western ethnocentric and limited diagnostic category that fails to capture the magnitude of torture as a trauma.

Vesti and Kastrup from the RCT concluded in 1995 that a substantial proportion of survivors developed symptomatology similar to that of PTSD but that others did not. This is consistent with the knowledge that there are individual differences in response to severe stress, which are in the early stages of being described. Basoglu et al., for instance, documented that perceived severity but not objective severity of torture was associated with PTSD, anxiety, and depression in torture victims. Impact of the captivity experience on the victim's family was the strongest predictor of PTSD symptoms. Age, personality, previous emotional and physical health, ideological and political commitment, and quality of the post-torture environment can affect the development of PTSD and other symptoms. The presence or absence of social support and the individual's perception of other persons' helpfulness are important variables for the reduction of the probability of full-blown PTSD.

Petersen et al., who reexamined 22 Greeks who had been tortured, found that eight of them met the criteria for the chronic organic psychosyndrome. These criteria included symptoms, experienced daily, of at least three of four types: (1) reduced memory or ability to concentrate; (2) disturbances of sleep; (3) emotional lability, anxiety, and depression; and (4) vegetative symptoms of the gastrointestinal or cardiopulmonary systems.

Some centers in developing countries placed an emphasis on the recognition of torture as a medical issue and the need for a formal account of the symptoms that follow severe violations of human rights. These centers pointed out that no compensation is currently given to victims and that there is no understanding in their populations or among their politicians that sequelae of torture exist. Therefore, the diagnosis of posttorture syndrome is important.

Regarding the existence of a torture syndrome, the International Rehabilitation Council for Torture

Victims (IRCT) acknowledges that influential researchers on torture have shifted their focus away from a unique torture syndrome and includes the psychopathological syndromes following torture as a subtype of the PTSD category. However, the criteria for PTSD are not sufficient for the categorization of the entire picture after torture. The psychological and physical profiles of PTSD and the posttorture state diverge considerably.

Symptoms that are core criteria for the definition of the posttorture state are described in the DSM-IV definition of PTSD as associated symptoms that are not necessary for a diagnosis of PTSD. These core symptoms are survivor's guilt with low self-esteem, changed personality (the continuity, wholeness, and autonomy of the self is negatively affected), physical sequelae without organic substrate, and many physical complaints without corresponding medical findings. Diffuse pain is a crucial element in the physical and psychological profile of the torture survivor.

Further research in this field might suggest that when the extreme traumatic stressor is interpersonal, the posttorture psychological and physical picture cannot be adequately described by the PTSD entity as it is currently defined. Systematic torture constitutes a more fundamental assault on the individual's self and assumptive world than random violence or other forms of extreme trauma, such as natural disasters. Therefore, there is a continuing need for specialized research on the hypothesis of a torture syndrome.

Rehabilitation Models

Today we know how to diagnose and document torture. The basic principles of diagnosis and documentation are given in the Istanbul Protocol, a UN manual on the effective investigation of torture. Also, today we have the knowledge of how to rehabilitate torture victims, and several different rehabilitation models have been developed.

The rehabilitation model most often used is the holistic approach, in which the psychological, somatic, social, legal, spiritual, family, and cultural aspects are taken into consideration. A point of conceptual importance is to consider torture survivors as not having any premorbid psychopathology.

The treatment principles of this approach are (1) to treat physical and psychological symptoms at the same time, (2) to secure the patient's trust and confidence, (3) to respect the individual, (4) to avoid situations that remind the patient of torture, and (5) to inform the patient carefully about examinations. Physical treatment in relation to diagnostic examination can be practiced, and fair results are possible even many years after torture. Repair of pain

is a very important goal for treatment, and the medical profession can in many cases accomplish that goal.

Treatment rehabilitation methods can be individual, couple, family, or group therapy or counseling, which is a method that, to some degree, takes into account a deeper understanding of the individual's experiences, giving relief and understanding and helping the person to solve problems and make choices.

Other forms of therapy include the following: psychological insight therapy, used for the meeting, the initial setting, the emotional phase, reintegration, and the end of therapy; psychological supportive therapy, used to deal with practical matters such as bodily dysfunctions, social matters such as housing and language, and integration matters, for refugees to get a basic understanding of their new country, as well as to provide balance between insight and supportive psychotherapy; special programs for children and families, such as couples therapy, family therapy, individual child therapy, group therapy, and network meetings; and the outreach method for screening and rehabilitation of torture victims. This last model has four points of importance: availability, accessibility, adaptability, and appropriateness. Availability refers to the services being available to meet the victims' health needs, both general and special. Accessibility means that the services must not be too distant or culturally insensitive. Adaptability refers to the likelihood of the project being acceptable to the refugees and therapeutically effective at the same time. Appropriateness is related to the question of whether a project is appropriate to the refugee groups covered by it.

The aim of all rehabilitation models is to facilitate the social functioning of the victim by strengthening adaptive coping mechanisms, discouraging nonadaptive processes, and facilitating access to social opportunities. Furthermore, it aims to facilitate the psychological treatment of traumatic experiences, loss, and bereavement by consoling, comforting, and protecting victims, sharing their experiences and emotions, recognizing their suffering and pain, and supporting them in their expression of grief when the first survival needs are satisfied. The final step is to treat the victims who have developed psychological disturbances.

Counseling is defined as a method that, to some degree, takes into account a deeper understanding of the individual's experiences, providing relief and understanding and helping the person to solve problems and to make choices. The counselor must respect the confidentiality of information given and must be capable of handling situations that are loaded with painful feelings without getting lost, and using them for the benefit of the client. He or she must also be skilled in analyzing problems, giving advice, and

knowing how to help the client arrive at his or her own decisions.

The counseling program is aimed at recruiting persons who are not health professionals such as doctors or psychologists to act as counselors. The program was created because in many countries health professionals are not available in sufficient numbers. However, other very capable professionals, such as teachers, journalists, monks, and nuns, will be able to learn the program and do a good job as counselors – not necessarily at the same level as the trained psychotherapist, but they will still be able to provide valuable help.

The aim of counseling is to increase awareness of experienced traumas and the reactions to them. Furthermore, it aims to provide relief from psychological suffering, to reduce aftereffects of traumatic experiences, and to help the victim regain control of life situations in order to become, once more, a fully integrated member of society.

The majority of torture victims cope with the help of family or community. Some of them, because of the severity of their symptoms, are not able to reintegrate into society and thus need assistance. Assuming the efficacy of treatment, an important challenge is to identify these victims and help in their communities.

Prevention of Torture

Prevention of torture can be differentiated into the steps of primary prevention, directed toward society itself, secondary prevention, directed toward groups within society, and tertiary prevention, directed toward individuals. Primary prevention of torture involves creating awareness of the problem by making torture visible. This can be done by establishing centers and programs for the rehabilitation of victims of torture. Information and education are also very important tools in the endeavor to create awareness.

Secondary prevention is directed toward teaching relevant personnel – military, police, and prison personnel – that torture always is prohibited, even when an order to torture is given.

The rehabilitation of torture victims serves as tertiary prevention against further violations involving torture, as the presence of rehabilitation services renders the problem visible. Torture may induce a belief in violence and loss of confidence in humanity, but rehabilitation can make people believe in humanity again. In the long run, rehabilitation can help the development of democracy and prevent future conflicts in favor of less stressful conditions.

The UN Convention against Torture contains all the necessary provisions to be able to punish perpetrators and to compensate, prevent, control, educate,

and inspect. This instrument was adopted in 1984 and came into force on June 26, 1987, which was proclaimed as the UN International Day in Support of Victims of Torture – a day not only for creating awareness but also for providing moral support to torture victims. It is a symbolic gesture that recognizes the victims and their families and honors those who did not survive the torture. The convention has been ratified by 141 countries, including all of those countries that had troops in Iraq in 2005 and until now.

Support from the UN, many governments, human rights organizations, nongovernmental organizations, and numerous initiatives is important in helping to break through the silence, insecurity, and indifference surrounding the issue of torture and will help make a stand for visibility, for openness, for acceptance among the boards of various foundations, and for the understanding of the necessity for moral rehabilitation of torture victims.

Impunity

The UN Convention states that torture is an offense under the criminal law of the country in which it occurs and that persons who are accused of torture are to be taken to court and, if found guilty, given penalties that take into account the grave nature of the offense. Article 60 of the Vienna Declaration points to the problem of impunity. It states that legislation leading to impunity for those responsible for torture and other grave violations of human rights should be abrogated.

Not much progress has been made in this area, although promising changes in public opinion in Chile and Argentina have led to ongoing legal proceedings against tyrant generals from the time of dictatorships. In several countries where torture takes place or has taken place, the identity of many of the torturers and those responsible for torture is well-known. Still, there are very few examples of these persons being punished, which is problematic for several reasons. First of all, this is troublesome for the moral rehabilitation of the victims of the torture. If the torturers are not punished, the victims will easily be left with the sentiment of being powerless and humiliated. Second, victims of torture go through unnecessary fear and distress when exposed to the risk of encountering their torturers in the streets. Third, impunity creates a twisted set of norms and values in society. Allowing the persons responsible for gross human rights violations to go free while at the same time hitting hard on conventional crime can lead to an increased brutalization of society. The veil of impunity is broken down slowly but surely, and medical professionals, with their ability to

diagnose and document the incidence of torture, have a key role to play in ensuring that torturers face prosecution and that the victims of torture receive proper rehabilitation and compensation.

The work of the Criminal Tribunal in the Hague should be mentioned. The work of the tribunal has shown the need for the establishment of a permanent international criminal court. This initiative can be a future platform for prosecution of those responsible for torture and thereby an important instrument for the eradication of torture and the moral rehabilitation of victims of torture. It is of great importance, however, that the protection and the support of the victims will be ensured by this court.

Conclusion

More than 30 years of professional, medical, and psychological work on torture have taken place. Today we may say that we have enough knowledge about the phenomenon of torture and enough conventions and declarations. Also, the experience available makes it possible to talk about torture and its effects in a more substantial and assured way. Sufficient basic knowledge (i.e., social analysis on a medical and psychological basis) allows us to make strong statements against the practice of torture. What is needed, however, is national and international recognition of the phenomenon of torture as well as recognition of the magnitude of the problem and its transgenerational effects and the necessity of implementation of conventions and declarations.

The Natural Stress of Driving
Driver Stress and Driver Behavior
Stress after Motor Vehicle Accidents
Aggressive Driving and Stress
Driving Stress and Road Rage
What Can Be Done to Reduce Stress in Driving?

Posttraumatic stress

Severe stress resulting from a dangerous situation, marked by anxiety, threat, fear, and helplessness; role impairment; and a preoccupation with the situation. This stress lasts more than 4 weeks.

Road rage

Situations in which drivers or passengers attempt to kill, injure, or intimidate another driver, another passenger, or a pedestrian.

Trait stress

Stress that is not situational but is related to ongoing personality and lifestyle factors and is an enduring feature of a person's life.

Glossary

Acute stress disorder Severe stress resulting from a dangerous situation and lasting up to 4 weeks.
Driver stress Stress that is not trait stress but relates specifically to the problems and challenge of driving.

The Natural Stress of Driving

Advertisements for new cars often show drivers racing along an open road, luxuriating in the comfort and phenomenal speed of the car. There are no other cars about, no backseat drivers, and no children

crying, “Are we there yet?” The reality of driving can be very different. Driving is often done in small cars with restricted space and difficult passengers. The environment is frequently noisy because of horns honking and the din of traffic. Attentional overload because of the complexity of modern cars may also create stress. There are often time restrictions: getting to work on time, picking up children, or making it to appointments. Many roads are congested, under repair, or closed altogether. There are strict performance demands – we must pay attention, avoid accidents, and cope with some other drivers’ wrath. Driving in heavy rain and in the winter in northern countries creates more stress.

Drivers are usually immobile and cannot get out, especially on freeways. Driving can also be dangerous because traffic lights change quickly and other drivers tailgate, cut in and out, or express their anger in other ways.

Many roads in or around cities are congested, and the levels of congestion are increasing in most North American cities. Highway building has not kept pace with car ownership. In North America, there are, on average, two vehicles per family, whereas there was only one vehicle per family for the previous generation. People are spending longer times in their cars and making longer commutes to work or school. Hence, they expose themselves to greater stress on the road.

Driving is often seen as stressful and difficult. In a recent Canadian study, 55% of drivers said that some of their driving was stressful and 15.7% said that half or more was stressful. Approximately 75% said that half or more of their driving was on busy roads and approximately 50% said that most or all of it was on busy roads. Considerable research shows that most drivers find driving on congested roads to be more stressful.

Some drivers have physical limitations that make driving more stressful for them. These include people with arthritis, with neurological or serious psychological problems, and who are elderly or disabled. Cars are not well designed to suit the needs of such people, and driving demands are difficult for them to fulfill. Elderly people often stop driving for physical or psychological reasons. However, the loss of driving capabilities often causes more stress and can lead to depression and social isolation for the elderly.

Driver Stress and Driver Behavior

Particular driving events cause stress among drivers, but many drivers have high levels of stress before they get in the car. Trait stress, or ongoing nonsituational

stress, has been much studied and several scales have been developed to measure it. Driver stress is greater in situations in which there is a lot of congestion and in which there is time urgency. Daily hassles contribute to driver stress. Drivers who recently had an illness, personal conflict, or bereavement are more likely to be in serious accidents.

Total driver stress varies because of the driving situation, personal disposition or trait stress levels, and nondriving events such as daily hassles. High levels of stress in drivers cause attention lapses, errors, and traffic violations. In several studies, driver stress has also been related to aggression and to involvement in accidents. However, most driver stress dissipates quickly once the driver gets out of the car.

Several methods of reducing driver stress have been investigated. Commuters who worked at a job with flextime had less driver stress than those who always traveled during rush hours. Drivers on flextime also felt less time urgency. Experimental studies have shown that drivers who viewed computerized highway drives that had more vegetation than human-made structures had less stress. Also, listening to music may reduce driver stress.

Stress after Motor Vehicle Accidents

Many drivers experience long-term stress after an injury in a motor vehicle accident (MVA). This stress can last many months or even years. The proportion of MVA victims having serious postaccident stress varies from study to study. Accident-induced stress is often assessed using the criteria from the *Diagnostic and Statistical Manual of Mental Disorders*. Acute stress disorder (ASD) is diagnosed within 1 month of the accident, and posttraumatic stress disorder (PTSD) is not diagnosed until after stress has lasted more than 1 month. Both involve subjective feelings of anxiety, fear, and helplessness; role impairment; and a preoccupation with the accident and its consequences.

Most studies of ASD and PTSD involve victims who were injured in accidents and assessed in emergency wards. In such samples, the rate of ASD varies from 10 to 40% and the rate of PTSD from 10 to more than 70%. The highest rates have typically been found in children injured in traffic accidents and people involved in litigation after an accident. Usually, victims with ASD are far more likely than others to develop the long-term stress syndromes seen in PTSD. However, some victims do not develop PTSD after having ASD. Most, but not all, studies found little correlation between PTSD and the severity of the injury.

In children, the likelihood of PTSD often relates to the seriousness that they attribute to the accident. Children after accidents are often afflicted with anger, alienation, thought suppression, and intensive memories of the accident. Most studies show that PTSD is much more common among female than male victims. PTSD may be also more common among those with lower socioeconomic status.

Postaccident stress is not found only among the victims of accidents. Parents also experience considerable stress if their children have PTSD. Also, PTSD, guilt and shame have been found among drivers who caused deaths in motor vehicle accidents. In that group PTSD and guilt were associated with the degree of responsibility the driver assumes for the accident and the severity of their punishment.

Post accident stress can last a long time and can also be related to other negative life events. Among PTSD victims, events such as loss of job or income, broken relationships, and serious illnesses were more common than among accident victims without PTSD. Because of legal liability and compensation issues, some postaccident stress may be faked or exaggerated. Some studies have shown that actors can fool evaluators of stress, especially if little corroborative evidence is available.

Aggressive Driving and Stress

Aggressive driving often causes stress for other drivers as well as for the aggressive driver. Aggressive driving typically involves tailgating; cutting in and out of traffic; preventing other drivers from passing; not moving forward on green lights; and shouting, gesticulating, or criticizing other drivers. If there is an attempt to threaten or intimidate other drivers or to damage their vehicle, this is referred to as road rage, but the two terms often overlap.

Angry or aggressive drivers are more likely to be male and young. Scales for measuring trait driver anger have been devised. Drivers who score high on these scales have more anger and anxiety and show less control over their aggression; they have more minor accidents and close calls but probably not more major accidents.

Driver anger is common and probably comes from feelings of stress during driving. Approximately one in four college student drivers reported being angry with another driver once or more per day. They rated stress from other drivers as equal to the stress of college examinations; traffic congestion, road construction, and finding a parking place were seen as less stressful.

Driving Stress and Road Rage

Road rage may appear to be a new cause of stress for drivers. However, it has been around for a long time. Sophocles in his play *Oedipus the King*, written in about 420 BCE, made road rage the reason that Oedipus kills his father. Also, the poet Byron was engaged in several incidents of road rage in the early 1700s. There are other historical cases as well. It is clear that mass media reports of road rage have recently increased in several countries, although one survey shows that incidents of road rage have been decreasing recently.

Road rage has no accepted definition; it has been defined as a situation in which a driver or passenger attempts to kill, injure, or intimidate another driver, another passenger or a pedestrian in a driving incident. Cases have been described in many countries in North America and Europe, and many have led to death or serious injury. A national study in the United States found that 30% of respondents had complained about other drivers; 17% had yelled at other drivers; 3% had chased other drivers; and 1–2% had gotten out of their cars to hurt other drivers, deliberately hit other drivers, or had carried a weapon. A study in Arizona found that 28% of respondents had aggressively blocked other drivers or followed them to retaliate. Approximately 11% always (4%) or sometimes (7%) carried a gun in their car, and hostile driving behavior was much more common for those with guns.

A Canadian study found that almost half of drivers each year were cursed at or had gestures made to them. Approximately 7.2% were threatened with personal injury or damage to their cars. This study and several others found that perpetrators of road rage are more likely to be younger and male. The victims and perpetrators of road rage are often the same people. However, there is a group of frequent perpetrators of road rage that accounts for almost all of the serious cases involving injury.

Road rage can be a very stressful event for its victims, especially if there is an injury. These victims may remember the event for long periods, modifying their driving behaviors to avoid later incidents. Victims of road rage often feel trapped and unable to get to safety. The immediate effects of road rage are fear, anxiety, anger, and annoyance. Victims report being shaken by it and sometimes being confused. Some victims have lingering thoughts and negative emotions after road rage, but most of this disappears in a few weeks unless there is a serious injury. Being the victim of road rage does make some drivers more cautious about driving.

Road rage is often associated with psychiatric morbidity and distress. In several studies, frequent perpetrators of road rage were found to have high rates of psychiatric distress and, more significant, stressful life events. It may be that frequent perpetrators of road rage bring their stress into the driving situation and, because of their high trait stress, are easily upset in traffic, lashing out at other drivers frequently.

Some studies have also shown that victims of road rage have high levels of psychiatric distress (i.e., anxiety, depression, and stress). Being a victim in a serious incident of road rage is likely to be traumatic for many drivers. The direct causal relationship between serious, injurious incidents of road rage and stress levels has not been examined, but such a relationship is highly plausible given what we know about stress after traffic accidents.

Road rage has been found to be more common among drivers who have more stressful driving experiences. Studies in Canada found that road rage was more frequent for drivers who often drove in congested driving conditions, whose driving was mostly done on busy roads, and who drove longer distances. Road rage was also more common for truck drivers; they drive in stressful situations with tight time schedules, and they are often tired.

Bus drivers have been found in several studies to be both the victims and perpetrators of road rage. They are often victimized by angry passengers, and such conflicts often lead to burnout and the desire to leave the job.

What Can Be Done to Reduce Stress in Driving?

Some of the stress drivers experience is trait stress that they had when they entered the car, and some comes from the experiences they have when driving. Reducing trait stress may require drivers to change relationships, work, and life styles and get better control over their lives. Reviewing these changes is beyond our scope here and we address only the stress that is directly related to driving.

Much stress in driving relates to traffic congestion, and most large cities are experiencing greater congestion. Fully automated transportation systems may eventually divert traffic from congested areas. A few cities are attempting to reduce congestion by increasing public transit, limiting rush-hour traffic, charging motorists for using certain roadways, and the like. Whether and how these measures reduce stress to reasonable levels is unclear at this time. More could

be done to allow flextime and reduce rush-hour travel. Roads could be built to be less complex for drivers, perhaps through traffic calming or other engineering changes.

Much of the serious stress from driving derives from involvement in accidents, especially those with injuries. In North America, the rates of fatal and injury-causing accidents have been declining for many years. The reasons for these declines are the greater use of seat belts and air bags, reduction in alcohol-related accidents because of strict enforcement, better licensing programs for young drivers, and engineering changes to make car crashes more survivable. The extension of these policy changes to other geographic areas could further reduce serious accident levels; so could more technical developments in cars and highways to make them safer.

Some driving stress comes from road rage and aggressive driving. Methods for reducing road rage include better education programs and anger management for convicted drivers as well as changes to vehicles. Some vehicle manufacturers such as Jaguar and Mercedes make cars that have radar systems to prevent tailgating, a common cause of road rage. These systems could be made more available. Cars could be redesigned to have voice-activated warnings when drivers raise their voices. Also cars could have lights that signal when drivers are becoming victims of road rage. Further modifications could also be made to track the perpetrators of road rage with global positioning systems (GPSs) and provide warnings to them. Much driver aggression relates to traffic congestion, and anything that reduces it will lower road rage, aggressive driving, and stress levels for drivers.

Glossary

Assignment The process society follows to designate a person as a male or a female.

Crossdresser A person who wears the clothing of the opposite sex, but does not self-identify as a transsexual.

Female-to-male (FTM) A person born biologically female, whose gender identity is male, who may undergo medical and surgical changes to confirm her male identity.

Gender dysphoria A person's persistent feeling of discomfort with the gender assigned at birth.

Gender identity A person's inner feeling of self-identification as male or female. Gender identity in some people may be intermediate, neither fully male nor fully female. Some people experience changes in

Gender identity disorder (GID)

Gender role

Male-to-female (MTF)

Reassignment

their understanding and acceptance of gender identity with the passing of time. A medical term, used as a synonym for transsexualism. GID is listed in the *Diagnostic and Statistical Manual of Mental Disorders*.

The category (male, female, or ambiguous) in which society places a person, based on physical characteristics and behavior.

A person born biologically male, whose gender identity is female, who may undergo medical and surgical changes to confirm her female identity.

Actions taken to change society's designation of a person as a male or a female. Transsexual people, crossdressers, and people of less-fixed gender identity; sometimes used to describe people who live in their desired gender role but do not seek surgical reassignment.

The process a person follows to live in his or her preferred gender; encompasses the physical changes brought about by hormones and surgical procedures, as well as the social changes of experiencing life and relationships in the new gender.

A person who experiences persistent and severe discomfort in the gender assigned at birth and who wishes to permanently live in the opposite gender role, with all the physical and social changes that role implies.

A crossdresser. This is an older term, used in the mid-twentieth century, and is not currently preferred by most people because it has been associated with a strictly sexual motivation.

Introduction and Definitions

We humans choose certain characteristics by which we define ourselves. The earliest and most essential definition is whether an individual is a man or woman, boy baby or girl baby. The distinction is established at birth, and nurseries are furnished in pink or blue. The basis for the distinction is our external appearance. Our genitalia determine the life we are expected to lead. All humankind is divided distinctly into these two groups: except when it is not.

In fewer than 1/1000 children – the true incidence is still not known – a persistent discomfort exists with the individual's physical sex. This discomfort is present from earliest memory. There is no identifiable behavioral influence to produce it. The child grows and matures unremarkably, to all external appearances; but the child's thought patterns and behavioral instincts are those of the opposite gender.

Such people live their childhood in frustration, knowing something is wrong but being unaware of the specific issue. Finally, due to logical reasoning or reading of someone else's experiences, the child or young adult awakens to the truth. The inner conflict is unrelated to behavior (lifestyle) or preference of sexual partner; rather, it is a conflict involving one's core identity. Medical terms such as gender dysphoria or gender identity disorder (GID) are sometimes used to describe the condition, but it is perhaps best known by the popular name, transsexualism.

Childhood Experiences of Transsexual People

Most adult transsexual people can remember feeling different from their same-sex peers. Before they knew the physical differences between boys and girls, and long before they began to experience feelings of sexual attraction, they knew they belonged in the opposite camp. Such knowledge can be terrifying in an environment where conformity is demanded and diversity is rejected.

Gender-variant behavior in children is not uncommon. Tomboy behavior in girls is usually tolerated better than effeminate behavior in boys. Many boys who play with dolls and other girls' toys grow up to become heterosexual men; some grow up to be gay men; and a few never consider themselves men at all, but they may fear for their safety if other children regard them as sissies. Childhood conformity and peer pressure are the first obstacles trans-gender people encounter in their journey toward transition.

Factors that Discourage Transition

Even stronger than a child's peer relationships are the bonds of family. Parents, brothers, and sisters are the most influential people in any child's life. In contrast to the previously held views of some mental health professionals, who theorized that transsexualism results from family dysfunction in early childhood, many transsexual people report normal and loving family relationships. Even so, it is rare for a transsexual child to feel comfortable discussing gender feelings with family. Perhaps the child loves his or her parents and fears hurting them with so startling a revelation; or perhaps the fear of punishment creates a determination to hide the truth. Such fears are not without merit – it is true that many parents are ill prepared to deal with such a revelation by a child.

Psychological stress is a natural result of the child's practice of denial, which many continue well into adulthood. Some children are so affected by the stress that their school progress is impaired. Others find temporary escape in retreat into books and studies. Music or other hobbies may serve as a welcome distraction from their worries. Some even practice denial so strongly that they seek the other extreme; for example, a boy may strive to excel at sports or to engage in high-risk behavior, placing himself in physical danger, to deny his feeling of being a girl. Indeed, some teens and young adults enlist in the military services in an effort to cure such feelings.

Even in childhood, religion may play a large role in the stress a transsexual child faces. Most religions teach absolute truths, and do not tolerate departures from those absolutes. The child is taught that his or her feelings are sinful or evil but that they can be overcome through the faith process. Most children are eager to believe such doctrine, hoping that they can be made normal so their parents and peers will accept them. When the religious experience fails to change a child's gender identity, the child is left with feelings of failure and self-doubt. A significant number of transsexual adults report so much despair as children or teenagers that they considered suicide.

The onset of puberty is a very stressful time for transsexual children. Their dreams of becoming normal members of their desired gender are severely challenged as female-to-male (FTM) people develop breasts and menstrual activity and male-to-female (MTF) youth experience growing to tall stature, beard growth, and a deepening voice. These physical changes require years of treatment through surgery, hormones, and electrolysis to correct – if they can be corrected at all.

The ultimate denial of an individuals' transsexualism focuses on their attempt to live a normal life through marriage and parenthood. In years past, transsexual young adults lacked the information and resources available today. Believing themselves doomed to a life of quiet unhappiness, they pinned their last hopes on marriage and family to cure them of their dysphoria. However, within a few years, they realized this too could not cure their sense of identity. Unfortunately, at this point other people have entered their lives in intimate roles, and any ultimate disclosure and transition will be disruptive to the entire family. Because of this, some people make the decision to delay transition until their children are older; this is the reason we see so many people begin transition after age 40. A decision to delay carries its own dangers; a child who reaches puberty before learning of a parent's transsexualism usually will react more negatively than a child who is made aware at a younger age.

The Transition Process

Eventually the transsexual person reaches a point of understanding – this is the way my life is going to be. Denial, family pressure, religious fervor, and even marriage have all failed to change the person's gender identity. The incredible pressure can be relieved only through acceptance and transition. The process of disclosure and beginning transition is sometimes called coming out.

This is perhaps the time of the most intense stress a transsexual person experiences. Every aspect of life is at risk: family, friends, status, job, and finances. The importance of advance planning becomes crucial. People who felt they would be warmly accepted may be devastated by the rejection they experience. Job loss, although not universal, is still very common. Income is gone, at a time when it is needed more than ever. The expenses of transition can be enormous; the psychological counseling alone is more than some people can afford, and the various surgical procedures may cost tens of thousands of dollars and very few are covered by insurance. Efforts to find a new job during transition, in the new gender role, are made more difficult because a lifetime of documentation – birth certificate, Social Security records, passport, diplomas, credit ratings – are all on record under the old name. Furthermore, a person in early transition still has behavior patterns from a lifetime of socialization in the birth gender. Such behavior may be overcome quickly for some people as they find the freedom to behave naturally as a member of their desired gender, but others struggle for years to shed male mannerisms. When added to a physical

appearance that still reflects the birth gender, the new mannerisms make it difficult for some to blend into society without attracting unwelcome attention.

For some, the stresses of transition prove too great. As a result of economic demand, family pressure, or the hope of a religious cure, some people abandon transition and return to their original gender role. For most, this return is temporary, and the transition process resumes once they are better prepared to cope with the stress.

Hormonal and Surgical Changes

During and after transition, the effects of cross-gender hormone therapy produce results that often are dramatic. FTM people experience a deepening of the voice and the growth of facial hair. The most obvious early effect of hormones for MTF people is breast enlargement. These effects are obvious to friends, family, and coworkers. At this point, transsexual people may feel a sense of relief because they no longer have to hide their identity or their plan to transition.

Of course, hormones do not produce a complete transformation to the new gender. Other physical differences, including skull and jaw structure, cannot be reversed by hormone treatment. Surgical procedures to eliminate prominent male jaw and chin shape, as well as the exaggerated prominence of the brows, can be of great help in allowing MTF people live normal lives without constant exposure. FTM people often seek mastectomy to make life less stressful.

Ultimately, the transition process culminates in sex reassignment surgery (SRS). In this operation, the surgeon removes some of the old sex organs and creates an appearance as close as possible to the desired gender. Most surgeons who perform SRS follow rather strict guidelines of patient selection to minimize the risk of postoperative regret.

Health Effects of Stress for Transsexual People

A number of physical and psychological effects may result from a transsexual person's decisions related to transition. Many effects occur prior to coming out. The stress of keeping hidden a life-changing truth may be a factor in all types of stress-related illness, including high blood pressure, migraine or other headaches, peptic ulcer disease, and inflammatory bowel disease.

The psychological impact of stress often manifests as chronic anxiety or depression. The degree of psychological distress may be so severe that the person cannot function normally in a work or school

environment. Anxiolytic medications, especially benzodiazepines, are often prescribed; even more commonly given are antidepressants. Some degree of depression is extremely common in transsexual people who have experienced rejection or loss.

Suicide, or suicidal gesture, is a continuing concern for many transsexual people. There are three periods when transsexuals are at greatest risk for suicide. The first occurs early in life, when the young person experiences despair from being unlike his or her peers; the stress of keeping such knowledge undisclosed is magnified by the failure of attempts to eliminate the dysphoria. The second period of high suicide risk occurs just prior to the person's acceptance of his or her transsexualism and decision to proceed with transition and is associated with the last attempt to avoid disclosure and to have, to outward appearances, a normal life. As already mentioned, acceptance and transition may relieve this stress and the associated depression.

The third period of high suicide risk occurs after the completion of transition. The person may have high expectations of success in the chosen gender, and some expectations are more likely to be realized than others. Most people find acceptance by society and may continue their careers or begin new ones. Some, however, lose their jobs and are unable to find employment sufficient to pay expenses. Family and friends may continue to reject the transsexual to the point of shunning the person. Perhaps most devastating, the transsexual may be unable to find a life partner whose love and acceptance is unconditional.

The psychological counseling included in a well-planned transition process should address these expectations so that transsexuals can consider how to deal with failure to meet them. Some people, unfortunately, view the counseling process as simply another obstacle to be overcome in order to obtain their desired surgery. The lack of attention to good counseling during transition may increase the likelihood of regret, depression, and even suicide in the years that follow.

Religion and the Transsexual Person

It is accurate to generalize that people whose religious heritage is liberal, or who have no religious affiliation, experience less stress with transition than people who come from a conservative religious background. This generalization can apply to conservative Christianity, and also to Judaism and Islam. Some churches, particularly the Roman Catholic church, have made specific doctrinal statements describing transsexualism as unacceptable. Other Protestant churches may include transsexualism with homosexuality and

issue a general condemnation of all gender and sexual diversity.

People who have been raised in such denominations experience a high degree of stress. Their religion tells them it is a sin to change from one gender to the other, and it threatens them with eternal punishment if they disobey. The church maintains that a person can, through faith, turn away from transsexualism and live a normal life. For many, the church is their major support network; the thought of being cast out is unbearable. Yet their life experience tells them otherwise – they have already experienced failure of their faith to bring about this change to normalcy.

These people are forced to choose between two difficult paths. Either they must continue to live in denial, experiencing the stress of secrecy and eventually reaching the point of having to face the truth, or they must face the truth early, risking probable rejection and becoming disillusioned with their faith. Many such people do find their way to more liberal, accepting churches, but others abandon their faith altogether and may become quite hostile to any form of religion.

Violence and Fear

It is not coincidence that transsexual people are more likely to be the victims of violent crime. Several factors explain this increased risk. Young, aggressive males, the group most likely to show violent behavior, have a high incidence of homophobia. If a homophobic male encounters someone who is visibly gender variant, he may feel his own masculinity is threatened; he may even feel the need to prove his manhood by attacking the queer.

In addition, when a person is not initially perceived as transsexual but is discovered to be so later, there may be anger because of the perception of having been deceived. Well-publicized cases of people such as Gwen Araujo and Brandon Teena, both of whom were murdered under these circumstances, illustrate the dangers of antitranssexual violence.

Such is the reality faced by transsexual people in our society. Most people take a healthy approach to such risks by avoiding situations in which the danger is apparent. Others may avoid all social occasions and relationships; their excessive fear of violent reactions prevents their having a normal social life.

Intimacy and the Transsexual Person

Many transsexual people find themselves alone at the beginning of transition. Either they have not been in a relationship or their spouse has refused to be a part of

their future plans. These people can benefit from the transition counseling process if they are willing to take the time to explore their future intimacy needs. Such exploration can be stressful in itself, however. People in transition learn that gender identity is independent of sexual orientation. An MTF transsexual person, for example, who was attracted to women prior to transition may ultimately seek intimacy with a man or with a woman. The problem comes when the desired partner has to deal with the reality of the transsexual person's past. A relationship with a man is often jeopardized by the man's feelings of homophobia and inability to get past the idea that his partner is not a real woman. Less likely, but also possible, is the failure of a lesbian relationship due to the female partner's similar feelings. It is possible to find love posttransition, but the increased difficulty of doing so is a great source of stress.

A different dynamic occurs when the spouse of a transsexual person chooses to remain in the relationship posttransition. What was initially a heterosexual relationship now is seen by the world as a homosexual one, with all the associated societal stress such couples encounter. The continued relationship becomes quite a strain on the spouse; for example, the wife of a MTF transsexual soon realizes that she cannot change her sexual orientation to lesbian, just as a gay person cannot decide to become straight. Couples who stay together after transition are the rare exception, and in general the two people involved are very mature and are strong and secure in their commitment to one another despite the stress of daily confrontation.

Aging and Death and the Transsexual Person

The subject of aging has only recently been discussed in depth among transsexual people because the number of people completing transition remained small until the 1980s. Now some people from that era are entering their 60s and 70s, and aging and health issues have begun to assume a prominence in their priorities and present unique stress situations.

Many elderly people count on their children or grandchildren for physical support, to attend to their medical needs, and to take them for doctor visits or hospital emergencies. Transsexual people may lack that support because of family rejection. They face the stress of finding other support among friends, and sometimes a network of elder transsexuals may form for mutual support. The idea of loss of independence is stressful for everyone, but especially so for people who may wear breast binders or hair-replacement systems.

The medical needs of the aging transsexual people are often unique. Physicians called to see a transsexual patient in an emergency may not possess the knowledge or the desire to provide appropriate treatment for these unique needs. It may be difficult to find a doctor willing to continue hormone therapy in an older individual or to screen for diseases associated with the person's birth gender.

A case was reported of an FTM person who developed ovarian cancer. He was rejected for treatment by several physicians, who could not accept a person who presented as a male but had ovaries. The patient eventually died from his disease, which had gone untreated unnecessarily. It is also possible (unlikely, but reported) for an MTF person to develop cancer of the prostate, and it is very rare for such people to submit to the usual screening blood tests.

End of life issues need to be addressed in transsexual people with special concern. It is very important that transsexual people have a partner or sympathetic friend to serve as health-care power of attorney. Likewise, it is important for them to have a will specifying how they wish to be buried or cremated. This will avoid the situation in which family members disregard the individual's stated wishes and bury him or her as the birth gender, even many years posttransition.

Conclusion

Transsexualism, more common than once thought, affects thousands of people who are subject to increased stress due to rejection or confrontation from family, friends, employers, religious institutions, and even total strangers. Coping with these stresses on a daily basis may make the transsexual person mature and strong, or it may be devastating. Understanding and acceptance may reduce the constant stress and enable the transsexual person to make valuable contributions to society.

Trauma and Dissociation

The Nature of Traumatic Memories

Amnesia and the Return of Dissociated Memories

The Neurobiology of Traumatic Memory

The issue of trauma and memory is central to the concept of posttraumatic stress disorder (PTSD). The *Diagnostic and Statistical Manual of Mental Disorders* (4th edn, DSM-IV) defines PTSD as being accompanied by extremes of remembering and forgetting. Because traumatic memories take on their extreme character only after a person has been exposed to overwhelming stress, laboratory studies using conventional stimuli seem to be of little guidance in clarifying what happens when people are traumatized. Because trauma cannot be simulated in the laboratory, the exploration of the relationship between trauma and memory depends on (1) collecting retrospective reports from traumatized individuals, (2) post hoc observations of people with trauma histories, or (3) provoking traumatic memories and flashbacks in the laboratory.

Trauma and Dissociation

Christianson and others have described how, when people feel threatened, they tend to experience a significant narrowing of their consciousness while remaining focused on the central details of their ex-

perience. This increasing narrowing of consciousness is a reflection of the dissociation of traumatized individuals. Dissociation at the moment of the trauma has been found to be the single most important predictor of the subsequent development of PTSD. Dissociation has been described as a concomitant of trauma during World War I and II and after accidents, rapes, and numerous other traumatic experiences. Although dissociation may have some adaptive value, it also seems to lead to a disintegration of the capacity to integrate the different perceptual elements of the traumatic experience. Extreme physiological arousal interferes with proper information processing and with the storage of information into narrative (explicit) memory. When people are overwhelmed, they may suffer from speechless terror in which words fail to describe what has happened. However, even though traumatized individuals may be unable to make a coherent narrative of the traumatic events, there may be no interference with implicit memory; they may know the emotional valence of a stimulus and be aware of the associated perceptions without being able to articulate the reasons for feeling or behaving in a particular way. Traumatic memories are split off from (dissociated) consciousness and are stored as sensory perceptions, obsessional ideas, or behavioral reenactments.

The Nature of Traumatic Memories

Under ordinary conditions, memory always is an active and constructive process. Whereas familiar and expectable experiences are generally easily integrated and memories of ordinary events are bleached in clarity over time, some aspects of traumatic events appear to get fixed in the mind, unaltered by the passage of time or by the intervention of subsequent

experience. However, the emotional valence of experience affects the accuracy of memory; reports of personally highly significant events are often unusually accurate and remain fairly stable over time. Evolution favors the consolidation of relevant information. Since late in the nineteenth century, clinicians have noticed over and over again that the memories of traumatized patients seem to consist predominantly of emotional and perceptual elements, whereas there appears to be an impairment of declarative memory. A series of studies on the memories of traumatized populations have demonstrated that, regardless of the nature of the trauma, traumatized individuals initially report having decreased verbal recall, whereas they are prone to reexperience the traumatic events in the form of visual images, kinesthetic sensations, sounds, smells, and extreme affective states. Whether we study people reporting childhood trauma, car accidents, rape, or other assaults or people who wake up in the middle of a surgical procedure, this pattern of recollection is consistently reported by victims with PTSD. This pattern of memory recollection suggests that traumatic memories are processed differently in the brain than memories of day-to-day experiences.

It is generally assumed that memories can easily be distorted and that verbal recall changes over time. Even so-called flashbulb memories tend to be modified with the passage of time. However, traumatized individuals tend to report that the content of nightmares and flashbacks remain the same. The author was able to show that memories of traumatic experiences change after effective treatment of PTSD but do not change if the PTSD remains untreated. There have been no reports in the scientific literature showing that the sensory and perceptual elements of traumatic memories change in quality with the passage of time; nor has the reverse been reported – that these elements of traumatic memories always remain unaltered.

Amnesia and the Return of Dissociated Memories

Amnesia following adult trauma has been very well documented following World War I and II, in accident victims, in concentration camp survivors, and in victims of torture. In recent years, the occurrence of amnesia following childhood maltreatment has been called into question. This controversial issue has given rise to numerous studies. At this time, there have been 39 published reports in peer-reviewed journals that have documented that anywhere between 20 and 80% of people with sexual abuse histories

suffer from amnesia for the event at some time during their lives; every published study of this population has found some percentage of subjects who suffered from amnesia. Precipitants for the return of these previously forgotten memories tend to be events or sensations that are reminders of the original trauma. Events such as witnessing someone else going through trauma similar to one's own, hearing about the similar trauma, seeing a movie, or being in the company of someone who reminds a person of him- or herself at the same age at which the abuse occurred tend to be the most common precipitants for the return of these memories. A well-known study by Linda Williams of a group of women with documented sexual abuse histories found that the memories of the women who had a period of amnesia and who later recalled their trauma were at least as accurate as the memories of the women who had always recalled their abuse.

The Neurobiology of Traumatic Memory

Based on animal research, it has been widely assumed that the massive secretion of neurohormones at the time of the trauma plays a critical role in the ways that traumatic memories are consolidated into long-term memory. The strength of hormonal stimulation at the time a particular event occurred determines how strongly the memory is laid down. This capacity helps organisms evaluate the importance of sensory input better and causes emotionally significant material to be accessed more easily. The problem in PTSD is that the capacity to access memories related to the trauma becomes too easy; the trauma is recalled whenever a person is exposed to a sufficient number of matching sensory stimuli, regardless of their current relevance.

Traumatic Memories Are State-Dependent

In people with PTSD, sensations reminiscent of the trauma, including states of high physiological arousal, selectively promote the retrieval of traumatic memories or precipitate behaviors associated with the original trauma. Classically, a Vietnam veteran may have a flashback during a Fourth of July picnic and behave as if he were back in Vietnam, but he might not respond to fireworks on New Year's Eve because only the sound, but not temperature, matches the sensations that accompanied the traumatic events. Biological research has shown that drugs that precipitate autonomic arousal, such as lactate or yohimbine, tend to precipitate panic attacks and flashbacks in patients with PTSD. These can be considered instances of state-dependent memory retrieval.

Functional and Neuroanatomical Correlates of Posttraumatic Stress Disorder: Implications for Understanding Traumatic Memories

A range of both neuroanatomical and functional changes have been documented in individuals with PTSD. Several studies have shown decreased hippocampal volume, as well as decreased volume of the corpus callosum in patients with abuse histories. Functional neuroimaging has shown that people with PTSD have an increased activation of the right amygdala when exposed to a traumatic stimulus, which is accompanied by a decreased activation of Broca's area. These findings suggest that the difficulty that many PTSD patients have in putting their memories into words reflect in abnormalities in brain activation. Although it is unclear at the present time what the precise clinical implications of these findings are, it is tempting to speculate that a decreased hippocampal volume may be responsible for the fragmented nature of traumatic memories. Altered cerebral lateralization, with increased right hemispheric activation, may be relevant for understanding dissociative phenomena.

History

Characteristics of Trauma Groups

Definition of Group Therapy

Group Process

Trauma Group Structure

Glossary

Arousal

A state of activated emotional activity.

Catharsis

Psychotherapy that encourages the discharge of pent up, socially unacceptable affects; the discharge of pent up emotions to result in the alleviation of symptoms or permanent relief of the condition.

Cognitive restructuring
Exposure

The identification and modification of maladaptive thought processes.

The disclosure of something private or secret; the act or instance of revealing or unmasking, for example, traumatic events.

Process

A systematic series of actions directed to some end (e.g., the uncovering of repressed emotions and memories).

Rap group
Talking cure

Peer group discussion.

The verbal interaction between therapist and patient (or peers) regarding the goal of uncovering hidden trauma; coined by Sigmund Freud.

History

Before presenting the elements of the trauma group, it is essential to understand the efforts to legitimize the trauma syndrome itself. Society has moved into a period when people are seeking the human suste-

nance that has been lost in the development of technology, the emergence of the megalopolis, and the increased complexity and depersonalization of societal structures. Individuals and communities are too often witnessing and experiencing the traumatic effects of the big hurts in life. Generalized angst in our societies prompts a search for a sense of community with intimate and mutually supportive human ties, a search for community that enhances the lives of individuals through a common purpose. Toward this end, more people are forging their own microcosms of community in the form of therapy or support groups. These come in many forms: action groups, which support collective or individual impact on societal institutions; interpersonal exploration groups, in which individuals seek to determine who they really are versus how they appear to others; and other groups pursuing strongly held common interests such as learning, experiencing or performing in a world of ideas and skills.

In the late nineteenth century, the disorder known as hysteria became the focus of a major inquiry. French neurologist, Jean-Martin Charcot studied the symptoms of hysteria, which resembled neurological damage: motor paralysis, sensory loss, convulsions, and amnesia. By 1880, he had demonstrated that these symptoms were psychological and could be artificially induced and relieved using hypnosis. Charcot's followers pursued the cause of hysteria. Rivalry in this pursuit was particularly intense between Janet and Freud. By the mid-1890s, Janet in France and Freud (with his collaborator Joseph Breur) in Vienna had independently arrived at strikingly similar formulations – hysteria was a condition caused by psychological trauma. While conducting explorations toward a cure, they found it necessary to speak to their patients. They found that unbearable emotional reactions to traumatic events produced an altered state of consciousness, which, in turn, yielded the symptoms of hysteria. Janet described these patients as being governed by subconscious fixed ideas – the memories of traumatic events. Breur and Freud, in an immortal summation, wrote that hysterics suffer from reminiscences.

By 1908, these investigators had also discovered that hysterical symptoms could be alleviated when the traumatic memories and intense feelings that accompanied them were recovered and put into words. Janet called the technique psychological analysis; Breur and Freud dubbed it the talking cure. Freud later recanted the link between hysteria and trauma, and the entire line of inquiry fell into neglect. The study of trauma came to a halt.

Reemergence of Trauma Investigation

The reality of psychological trauma was forced into the public consciousness again by the catastrophe of World War I, although the primary mental health conclusion at that time was that soldiers who developed a traumatic neurosis were at best constitutionally inferior human beings and at worst cowards and malingerers. Within a few years after World War I, medical interest in the subject faded again. In 1922, a young American psychiatrist, Abram Kardiner, took up the case of traumatized soldiers. He developed the clinical outline of the trauma syndrome as it is understood today.

With the casualties of World War II came a revival of medical interest in combat neurosis. Various studies led to the conclusion that the strongest protection against this overwhelming terror was the degree of relatedness between the soldier, his immediate fighting unit, and their leader. Their microcosmic community recreated treatment strategies, evolved during World War II, that were designed to minimize the separation of the afflicted soldier and his comrades. In the quest for a fast and effective method of treatment, hypnosis was used, as it had been in earlier work on hysteria. Under hypnosis, the talking cure was used with a focus on recovery and cathartic re-experiencing of traumatic events and their attendant feelings of terror, rage, and grief.

Systematic large-scale studies of the long-term effects of combat were not undertaken until after the Vietnam War. The use of groups to treat trauma was pioneered with Vietnam veterans. By the mid-1970s, hundreds of informal rap groups had been organized.

Characteristics of Trauma Groups

From their beginning, trauma rap groups were different and innovative. They had three guiding principles: (1) The groups were formed around an affinity, or the coming together of people who shared an historical perspective or personal experience; (2) the task of the facilitator was to be empathic and manifest a presence at all times of full engagement, openness, and interaction and not to serve merely as a sounding board; and (3) the veterans had to assume responsibility for self-generation, that is, to initiate their own process and conduct groups largely on their own terms.

Early proponents of trauma treatment in the group model illuminated six characteristics that are shared by veterans active in the groups.

1. They have a pervasive guilt from which they cannot escape. Its nexus resides in having lived

when others from both sides of battle have been killed or severely maimed. The guilt leads to a pathological desire to atone for the sin of having survived. To this end, they become involved in reckless forms of self-punishment such as substance abuse or one-car accidents that are just a shade less determined than actual suicide.

2. They have a feeling of being scapegoats, having been used and betrayed.

3. They have a generalized rage at society and at the individuals they believe have duped and/or manipulated them.

4. They have undergone combat brutalization, a method of military training aimed at creating the most effective soldiers by numbing the emotional processes that could interfere when the need to fight or kill arises. This learned detachment leads to the fifth characteristic.

5. They are alienated from their own humanity and withdrawn from others. This alienation inevitably leads to the sixth and most devastating characteristic of all.

6. They have a profound inability to love, accept affection, or to be intimate with others.

These characteristics predominated then, and they prevail today as the symptoms we most often see presented in treatment for trauma.

Definition of Group Therapy

Group therapy is psychotherapy practiced ideally in a group of 8–10 members/participants. The group itself becomes an important entity in the treatment of its individuals. The group collective assists its members by guiding, constructively criticizing, and offering therapeutic suggestions and support. It is the application of psychotherapeutic techniques within a small group of individuals who share similar experiences and have difficulty in responding to them. Each group has one or two leaders or facilitators whose role it is to guide and direct the group discussion or processing of problems in an attempt to promote personal growth and favorable behavioral change.

Types of Therapy Groups

There are different kinds of therapy groups. They may deal with a variety of issues including interpersonal conflicts, addictions, or trauma. The Department of Veterans Affairs National Center for Posttraumatic Stress Disorder (PTSD) has written that the best option for most PTSD patients is group therapy. In the trauma group, patients discuss with others their traumatic memories, symptoms of PTSD, and functional deficits. This approach has been most

successful with combat veterans, rape and/or incest victims, and natural disaster survivors. Indeed, the group model has been so effective that it lies at the core of the ever-growing self-help movement. The trauma group promotes discovery of, insight into, and eventually integration of the traumatic event.

Group Process

Trauma groups employ two important aspects of trauma recovery: the talking cure and the healing benefits of modeling supportive interactions with others in small-group cohesion. Survivor groups typically comprise 8–10 people meeting regularly to provide support and encouragement to one another. They accomplish a number of steps in healing by confronting alienation and estrangement. Survivors begin to realize that they are not alone in their reactions. Their feelings are normalized, and they begin to feel that they are part of something rather than being different or separate. The group offers a sense of community and a feeling of security.

Cognitive Restructuring

An important function of the trauma group is to destigmatize the traumatic experience. It focuses on exposure, which is the repeated disclosure of the event(s), and guides patients to a more realistic view of themselves and their world (cognitive restructuring). In addition, the trauma group combines the strengths of its members by having them each share coping skills and ideas that have benefited them. Most important, the group creates a milieu in which members can learn to trust and establish an ability to enter into relationships again. The group provides a laboratory for trusting others and, in time, patients can generalize this trust and begin to form healthy relationships in the outside world. The group model has been shown to be inappropriate and not helpful with patients who are suicidal, homicidal, violent, actively abusing drugs, or self-mutilating.

Trauma Group Structure

The foundation of the trauma group rests on exposure, cognitive restructuring, and the use of the traumatic narrative. It allows for reexperiencing trauma in manageable doses. The methods used in each phase share the common feature of helping anxious patients confront their most fearsome recall with the goal of reducing irrational fear (anxiety). Exposure has been the standard of treatment for anxiety disorders for several decades. The trauma group, in phases, employs both exposure and cognitive therapy to extinguish the prevailing pathological fear

structure in the survivor's memory. The effective group process offers the patient corrective trauma-related information. This, in turn, provides an opportunity for patients to begin the process of desensitization, or adaptation to the trauma.

Repeated reliving of the trauma reduces it to a specific occurrence rather than a generalized representation of the world as a universally dangerous place and reduces patients' self-image of incompetence. The trauma group is structured to merge exposure with cognitive therapy; this merger yields the desired therapeutic effect – the integration of dissociated trauma material and newly acquired corrective information.

Phases of the Trauma Group

Phase I The first phase of the trauma group addresses the issues of trust and personal safety. Patients are given assurance that group content is absolutely confidential and that no violence will occur during group sessions. Participants learn quickly that they are in control and that the model involves small steps toward emotional passages. "Managing small doses of awareness" becomes the mantra of the group. Patients know that they are in control, an essential element derived directly from the rap group model. During this phase, patients build trust with the facilitator(s) and other group members. They learn that the group medium fosters support and mutual healing, and the trust emerges slowly, with each emotional victory. Emphasis is on the present – the here and now. The importance of self-care, stress management, and anger management is highlighted. The process confronts the Lone Ranger syndrome and encourages each member to become part of the cohesive unit. The beginning steps of trust and bonding begin to surface; healthy and supportive relationships are born and nurtured. The patients demonstrate emotional growth, indicated by patience, courage, and the desire to confront their fears. They have constructed a healthy emotional platform from which to begin the arduous task of thawing freeze-dried traumatic memories.

Phase II The second phase of the trauma group is the narrative/trauma phase. Survivors have stories that must be revealed to themselves and to others. The fundamental human need to share and connect (Maslow) is enacted in phase II. It becomes about exposing and facing the hidden horror. Initially, narratives can be fragmented and distorted. Refining them in a controlled, supported environment reveals the conflicts between the memory and the actual event(s). The narrative helps to thaw out the frozen memory. It offers an important way to desensitize

patients to the enormous emotional overload. By repeated telling of the story and significant group feedback, a linear narrative emerges and patients begin to see the event more clearly and can begin to integrate the frozen memory into their broader life picture.

Phase III The last phase of the trauma group is the reconnection phase, or Life 101. A desire and ability to return to a productive, healthy, and satisfying life style returns. The symptoms of PTSD have become manageable. Patients can bear the feelings associated with the traumatic memories because they are now in a position of authority over them. The memory, with all of its dreaded darkness has become a coherent story linked to an appropriate affect. Patients, unlike the carpenter with a hammer, no longer see everything as a nail. Long-held perceptions regarding self and the world have been altered. Often, the survivors can rid themselves of the hero-villain paradigm of life. They can once again embrace a humanity that has been out of reach for so long. Patients begin to accept that life is imperfect and that in life both love and horror can coexist. Patients move from alienation from themselves to being the narrator of their own lives. Reconnecting means repairing the covenant of trust with themselves, which was broken at the time of trauma. It means being active, engaged, and prosocial. It means serving others and striving to make the world a better place. Life can become meaningful and fulfilled with a balance of joy, laughter, and sometimes tears. Most important, survivors can once again give and receive love. There is life after trauma.

Conclusion

Glossary

<i>Acute stress disorder</i>	An anxiety state lasting up to 4 weeks following a traumatic event.
<i>Acute stress reaction</i>	An acute and time-limited (up to 48 h) anxiety state following a traumatic event.
<i>Animal models</i>	Experiments in which animals are used to mimic and study human diseases.
<i>Combat stress reaction</i>	An acute stress reaction that develops on the battlefield.
<i>Gulf War</i>	The 1991 war in which the United States and the allied countries fought against Iraq following its invasion of Kuwait.
<i>Intifada</i>	Recent Palestinian campaigns directed at ending the Israeli military occupation (from <i>انتفاضة</i> <i>intifāḍah</i> , shaking off; Arabic for uprising).
<i>Posttraumatic stress disorder (PTSD)</i>	A chronic disorder that develops in survivors of traumatic events.
<i>Stressful life event</i>	An event that might cause emotional distress.
<i>Traumatic event</i>	A life-threatening event.
<i>Yom Kippur War</i>	The 1973 war in which Egypt and Syria attacked Israel.

Introduction

Emotional trauma and stressful life events have been implicated in the development of psychiatric disorders, particularly anxiety and depression. Traumatic

events differ from stressful life events in that they involve a direct threat to life or physical/psychological integrity. Posttraumatic responses can be diverse, but the most typical form of psychiatric morbidity resulting from exposure to a traumatic event is posttraumatic stress disorder (PTSD). It is estimated that at least 50% of the people in Western countries are exposed to traumatic events during their lifetime. Because PTSD occurs in approximately 10–20% of the individuals who are exposed to a traumatic event (the majority eventually adapt), the estimated life prevalence is 10% of 50% (i.e., 5%). Indeed, epidemiological studies show that 1–3% of the adult population in the United States suffer from PTSD. The finding that only a fraction of those exposed to traumatic events develop PTSD suggests that the traumatic event is necessary but not sufficient for its development and that additional factors are important in determining the individual vulnerability of trauma survivors to developing PTSD.

The study of human responses to trauma has been intimately associated with the history of wars in the twentieth century. There have been anecdotal accounts of posttraumatic responses in soldiers in the American Civil War and other wars in the nineteenth century, but World War I (1914–1918) is clearly the cradle of the modern study of trauma and its consequences.

Only in the last 2 decades has trauma research evolved to focus on civilian populations that have been exposed to violence, sexual abuse, terror activity, traffic accidents, and health conditions (e.g., heart attacks), which have all been shown to cause PTSD and are responsible for the high prevalence of the disorder in civilians.

Israel has become, since its establishment in 1948, a live laboratory for the research of trauma and PTSD. The horrors of the Holocaust and its emotional scars in the survivors, followed by seven wars and waves of terror, have unfortunately served as an experimental field for the study of trauma and its consequences. This article reviews key findings from studies done in Israel on trauma and PTSD during the last 2 decades and highlights their contribution to the existing body of knowledge in this field.

Posttraumatic Reactions in Holocaust Survivors

The Holocaust is an unparalleled event in human history that has left enduring emotional scars in all

its survivors. Most Holocaust survivors were able to readjust surprisingly well and restore their lives, whereas others were not able to overcome the dreadful events, which continued to cast a shadow on their entire life, making it impossible for them to regain security and emotional well-being.

Studies of Holocaust survivors were done mainly in the 1960s and 1970s, before the era of modern trauma research and the conceptualization of the definitions currently used in the field. This, and the fact that many of the survivors have already died and those who are still alive are in their 80s, explains the relative paucity of updated data on posttraumatic responses in Holocaust survivors.

Combat Stress Reaction and Posttraumatic Stress Disorder in War Veterans

The Yom Kippur War and Lebanon Wars

In contrast to the earlier wars in the short history of the state of Israel (1949, 1956, 1967), which were not studied systematically in the context of traumatic stress, some of the soldiers with combat stress reaction (CSR) during the Yom Kippur (1973) and Lebanon (1981) wars were identified early on, received treatment, and were followed over time, so that data could be collected about the short- and long-term consequences of exposure to traumatic events during wartime. The Lebanon war constituted the first systematic effort to apply and study the principles of proximity immediacy and expectancy (PIE) in the treatment of soldiers who developed CSR. These treatment principles, originally formulated during trench combat in World War I, are based on experience with soldiers who developed CSR and were removed from the artillery range. The basic premise of this treatment approach (which was never tested with appropriate scientific tools) is that the chances of overcoming CSR are highest when treatment is applied in proximity to the war zone, as early as possible after the condition develops, with an expectancy for full and rapid return to functioning. These relatively simple treatment principles were applied by the medical teams, including psychologists and social workers, that were part of the fighting units and were specially trained to deliver this treatment. Due to constraints of the war situation, the treatment was not available to all soldiers who developed CSR, and thus the prospective short-term and long-term outcome of treated and untreated veterans with CSR was limited. The data that emerged from these studies indicate that (1) CSR constituted approximately 15–25% of war-related casualties; (2) only

one-half of the veterans who eventually developed PTSD applied for treatment in the front line; (3) among those who were treated according to the PIE principles, 15–20% eventually developed PTSD; and (4) the long-term beneficial effects of the PIE treatment need to be further explored.

Prisoners of War

Prisoners of war (POWs) from these wars were also studied. Twenty years after their captivity, 13% of the POWs still suffered from PTSD, compared to only 3% in a comparison group of combat veterans. It was also evident that recovery from PTSD among POWs was slower and incomplete compared to the control group.

Secondary Traumatization

Life often becomes literally a nightmare for many of those suffering from PTSD. What has been realized only in more recent years is the impact of the disorder on those living with the victims and on their caregivers. It has been shown that both close family members and therapists who are exposed to the traumatic memories and suffering of the victims tend to develop emotional distress and PTSD-like symptoms, including intrusive thoughts, emotional numbing and avoidance, and symptoms of increased arousal. This phenomenon was called secondary traumatization.

Traumatic Injury and Posttraumatic Stress Disorder

Another issue that received attention during the last years of the war activity in Lebanon, before the final withdrawal of the Israeli army from Lebanon, was the effect of traumatic injury on the development of PTSD. The assumption that bodily injury inflicted during the trauma does not increase the risk for PTSD, and in fact might even serve as a protective factor, prevailed among trauma experts in the past. It was believed that, being visible, the injury engenders sympathy and support from the environment to a greater extent than the psychic wounds of the trauma. It was further postulated that the injury also provides a focus for coping that distracts the subject's mind from the trauma and, last but not least, in the case of war, evacuation due to the injury removes the source of anxiety and danger from the soldier by providing a legitimate escape from the stressful situation. However, when injured and uninjured soldiers who were involved in identical war activities in Lebanon were compared for posttraumatic symptoms, it was found that the injured soldiers had an eightfold higher risk for developing PTSD compared to their uninjured peers. These findings clearly demonstrate that injury

in the context of trauma exerts an additional risk factor and increases the risk of PTSD. Possible explanations for this finding are that injury amplifies the sense of horror and perceived threat for life. In addition, the medical procedures and the pain resulting from the injury create an additional source of stress and serve as retrieval cues for the traumatic memories.

Lessons from the Persian Gulf War

During the Persian Gulf War in 1991, the entire population in Israel was, for the first time, under a direct threat of warfare and missile attacks. This constituted a serious psychological threat to the civilian population that had not been directly involved in war activity until that time. Data are not available about the prevalence and the magnitude of acute traumatic stress reactions in the entire population during that period. However, data are available about those who were evacuated to hospitals following the missile attacks.

Over a period of 2 weeks in the winter of 1991, approximately 40 surface-to-surface Iraqi SCUD missiles were launched and sent to Israel, targeting mainly the central coastal region of the greater Tel Aviv area. The uncertainty about the place, time, and type of warhead (chemical, biological, or conventional) was a source of stress and anxiety for the entire population, mainly in the targeted region. Furthermore, it was the cause of many traumatic stress reactions at or near the sites where the missiles hit. Approximately 800 citizens were evacuated to regional hospitals following these attacks, of which approximately 40% were diagnosed as psychological casualties. In addition, approximately 30% of the evacuees had mistakenly injected themselves with atropine, an antidote used during chemical warfare. These findings indicate that psychological responses constitute a significant portion of the casualties resulting from this kind of warfare and that rescue teams and hospitals have to be trained and prepared accordingly.

The specific psychological responses of mothers and children following the missile attacks were also studied. In a survey done 2 years after the war, families that were evacuated from homes that were destroyed or damaged in the missile attack were compared to families who did not have to leave their homes and were not directly affected by missile attacks. Mothers and children from the evacuated families manifested more posttraumatic symptoms and higher degrees of emotional distress. Stress symptoms tended to decrease over time in the displaced children from the evacuated families but not in their mothers. No differences in the children's adaptive behavior in the two groups were observed. Mothers

who manifested more posttraumatic symptoms during the war were found to be more symptomatic at the follow-up, and the degree of stress in the children correlated with the mother's symptoms. These findings suggest that a maternal stress-buffering capacity is crucial for children's effective coping with stressful situations. The degree of family cohesion was also found to be an important factor in the successful coping of these children with the stressful situation. A follow-up study 5 years after the Gulf War showed significant decrease in posttraumatic symptoms in the evacuated children.

The Impact of Terror on Traumatic Stress Responses in the Israeli Population

The years 1987–2005 of the Israeli-Palestinians conflict, known as the Intifada, have exposed the civilian population in Israel to an unprecedented degree of violence and direct threat to lives as a result of numerous terror attacks and suicide bombers. The peak of the terror wave was in the years 2000–2004, and during this period 963 Israelis were killed and more than 6300 were wounded in hundreds of terror attacks and many more were directly exposed to the impact of terror and violence with direct threat to their lives.

A survey conducted in 2002 revealed that 16% of a representative population sample of approximately 560 people had been directly exposed to a terrorist attack and 37% had a family member or a friend who had been exposed. Ten percent of the sample met the diagnostic criteria for PTSD and approximately 60% reported feeling depressed. However, approximately 80% of the respondents expressed optimism about their personal future and 67% were optimistic about the future of the country. Seventy-five percent of the respondents expressed self-confidence about their ability to function in a terrorist attack. Despite the fact that many of the respondents expressed a low sense of safety with respect to themselves and their relatives, only 5% reported a need for professional help. Altogether, these findings indicate that, considering the nature and length of the Israeli traumatic experience during this period, the psychological impact of the situation may be considered moderate to low, and despite the fact that participants showed distress and a lowered sense of safety, only a minority developed psychiatric distress. These apparently discrepant findings may be related to a process of habituation and to effective psychological coping mechanisms.

Interesting differences were evident between urban communities exposed to different levels of stress and terror activities. To a certain degree, those communities

that were exposed to more violence and terror activity showed better coping abilities and lower degrees of personal distress than did communities with low exposure when facing stressful conditions.

Gender differences in the prevalence of PTSD have been reported. Although men are more frequently exposed to traumatic events, most studies have reported higher rates of PTSD among women. Studies done in Israel during 1999–2003 showed lower rates of direct exposure to terror among women, yet, compared to men, women reported more subjective distress and more posttraumatic symptoms and were using more coping strategies to overcome the distress. Sixteen percent of the women (but only 2.5% of the men) in the Israeli survey met the full criteria for PTSD.

Neurobiology and Psychophysiology of Posttraumatic Stress Disorder

Sleep and Posttraumatic Disorder

Sleep complaints are among the most frequently reported symptoms in PTSD. Difficulty falling asleep, restless and interrupted sleep, and recurrent dreams with nightmares are very common complaints.

Sleep disturbances and complaints of disrupted sleep in the early aftermath of the trauma have been associated with higher rates of PTSD later on. Some people with PTSD tend to develop a reversed sleep cycle, staying awake most night hours with a tendency to oversleep during the day. However, despite the high prevalence of subjective sleep complaints in PTSD, objective sleep measures have shown inconsistent findings. Unlike major depression, in which shortened rapid eye movement (REM) sleep latency is a well-established finding, polysomnographic sleep studies in patients with PTSD have not defined a clear pattern of sleep alterations that might be correlated with the subjective complaints of the patients. Some studies have shown fragmented REM sleep, whereas others have shown reduction in slow-wave sleep or increased awakening thresholds from slow-wave sleep. However, these findings are inconsistent. It has been suggested by some researchers that the subjective complaints of disrupted sleep in PTSD that are not corroborated in the polysomnographic studies are due to an altered sleep perception, namely, that the neurophysiology of sleep is not disturbed but there is a state of sleep misperception that causes a dissociation between an apparently normal sleep pattern and its altered perception by the subject. This could explain the relative inefficacy of sleep medications in PTSD, which is a widely acknowledged phenomenon and results in the excessive use and often abuse of sleep medications in these cases.

Physiological Arousal and Posttraumatic Disorder

Symptoms of increased arousal and exaggerated startle response are characteristic of PTSD. When exposed to loud tones 1 and 4 months after a traumatic event, subjects who developed PTSD showed a greater heart rate response, altered skin conductance, and eye muscle electromyogram (EMG) responses when compared to subjects who did not develop PTSD after a traumatic event. No such differences were evident between the groups immediately after the trauma, indicating that these findings were state-dependent and characteristic of trauma survivors who develop PTSD.

Furthermore, subjects with PTSD failed to show the habituation in response to repeated loud tones that is normally seen and was evident in the comparison subjects who did not develop PTSD. This phenomenon could reflect a more generalized inability for habituation of stressful signals; the recurrent intrusive memories in PTSD could be considered to be a failure of habituation to the content of the traumatic memories.

Heart Rate and Heart Rate Variability in Posttraumatic Disorder

Increased heart rate is a determinant of physiological arousal seen in PTSD. Subjects who develop PTSD have been shown to have higher heart rates during the immediate aftermath of the trauma compared to traumatized individuals who do not develop PTSD. The elevated heart rate is caused by the increased noradrenergic tone, suggesting that increased noradrenergic activity immediately after the trauma may play an important role in the neurobiological processes involved in the development of PTSD. From a clinical perspective, this finding suggests that elevated heart rate immediately after the trauma is a predictor of PTSD.

Animal Model for Posttraumatic Stress Disorder

The validity of an animal model for psychiatric disorders is often questionable. However, there is a clear advantage for PTSD because an exposure to threat (a predator, in the case of a rat) certainly addresses some of the validity issues that might be problematic in animal models of other psychiatric disorders. An animal model of PTSD composed of exposure to a predator (the smell of a cat, in this case), applying behavioral cut-off criteria to differentiate between the maladaptive rats and the well-adapted rats was developed in Israel in 2003. This enables investigators to further advance PTSD research by examining

questions such as early life adversities, stress-dependent increase in cortisol levels, and therapeutic (preventive) effects of early administration of medications that are often used in the treatment of PTSD, such as selective serotonin reuptake inhibitors (SSRIs).

Conclusion

The unique (although unfortunate) combination in Israel of having many Holocaust survivors, several wars, exposure to repeated waves of terror, and the presence of a pure form of PTSD (i.e., very low rates of alcoholism and drug abuse), coupled with the expertise in research, have helped Israeli researchers and clinicians to develop vital and advanced treatment and research in stress-related disorders, including acute stress reaction, CSR, and PTSD. The key findings have called into question some of the accepted notions of PTSD. Issues such as a direct linkage between terror exposure and PTSD were not found. The use of PIE principles in the modern battlefield seems to require further research, as do the apparently strong link between physical injury and PTSD and the lack of objective findings in a sleep laboratory in regard to sleep disturbance in PTSD. The development of a new animal model for PTSD, with the focus on behavioral cut-off criteria, along with further research in regard to the genetic vulnerability to PTSD, may pave ways to deepen our understanding of this intriguing phenomenon.

Introduction: Origin of the Trier Social Stress Test (TSST)

Description of the TSST Protocol

Overview of Sources of Intra- and Interindividual Differences

The TSST in Clinical Populations

Conclusions

Glossary

Cortisol

A glucocorticoid hormone produced by the adrenal cortex. Cortisol exhibits a pronounced circadian rhythm and responds to a wide range of stressors. It has many physiological effects and virtually every nucleated cell in the body has cortisol receptors. It is predominantly (90–95%) bound to proteins in blood; only 5–10% of the total plasma cortisol circulates biologically active as unbound, free cortisol.

Hypothalamic-pituitary-adrenocortical (HPA) axis

A central regulatory and control system of the organism that connects the central nervous system with the endocrine system. Under stress, the hypothalamus secretes corticotropin-releasing hormone, which provokes the release of adrenocorticotrophic hormone (ACTH) from the pituitary. ACTH triggers the secretion of cortisol from the adrenal cortex. The functioning of the axis is controlled by several negative feedback loops.

Psychosocial stress

Psychological stress that exerts physiological, behavioral, and/or verbal-subjective stress responses as a result of stressful social interactions, which often involve social-evaluative threat (in contrast to stress responses provoked by physical exertion or pharmacological stimulation).

Social-evaluative threat

Social component of a psychological or a psychosocial stress task in which task performance could be negatively judged by others. Stress tasks containing the two components uncontrollability and social-evaluative threat are associated

Sympathetic-adrenal-medullary (SAM) axis

Trier social stress test (TSST)

with the largest hypothalamic-pituitary-adrenocortical axis stress responses and the longest recovery times.

Sympathetic nerves, originating in the central nervous system, stimulate the adrenal medulla, which in turn secretes epinephrine and norepinephrine. These catecholamines mobilize energy-producing mechanisms quickly and downregulate less important organ functions.

A standardized stress protocol for the induction of moderate psychosocial stress in laboratory settings, which mainly consists of a brief preparation period (3 min) and a test period in which the subject has to deliver a free speech (5 min) and perform mental arithmetic (5 min) in front of an audience. The TSST can be applied to younger and older adults, to children as well as clinical populations. The TSST is one of the few available stress protocols that satisfies the criteria of a motivated performance task that combines elements of uncontrollability and high levels of social-evaluative threat.

Introduction: Origin of the Trier Social Stress Test (TSST)

Stress is one of the most significant health problems in the twenty-first century. This explains a pressing need for investigations into the biological pathways linking stress and health. Besides the sympathetic-adrenal-medullary (SAM) axis, the hypothalamic-pituitary-adrenocortical (HPA) axis is the major physiological stress response systems in the organism. Since alterations in HPA axis stress responses appear to be a close correlate or even a determining factor of the onset of different diseases or disease progression, the characterization of an individual's HPA axis response pattern to psychosocial stress appears to be of major interest. For such research agenda, a novel research tool was needed since available laboratory stress protocols yielded insufficient activation of the HPA axis. A stress protocol that was potent enough to induce significant changes of endocrine and cardiovascular parameters in the majority of subjects tested was eventually developed and termed the Trier Social Stress Test (TSST). Over the past decade, well over 4000 TSST sessions were performed in many laboratories worldwide. Thus, the TSST has become a standard protocol for the experimental induction of psychological stress

in healthy subjects as well as in clinical populations, investigating a wide range of different outcome variables ranging from subjective-verbal stress reports to objective behavioral and biological stress responses, including parameters of the HPA and SAM axis and the cardiovascular, immunological, and blood coagulation system.

Recently, Dickerson and Kemeny conducted a meta-analysis based on 208 laboratory studies of acute psychological stressors in order to delineate the essential situational elements capable of eliciting HPA axis responses. The results show that motivated performance tasks elicit cortisol responses if they are (1) uncontrollable, (2) creating a context of forced failure in which a subject is unable to avoid negative consequences or cannot succeed despite his or her best effort, or (3) characterized by a social component called social-evaluative threat, in which task performance could be negatively judged by others. Tasks containing both components (uncontrollability and social-evaluative threat) were associated with the largest HPA axis stress responses and the longest recovery times. These meta-analytical findings fit to the theoretical reasoning (based on the social self-preservation theory) that “uncontrollable threats to the goal of maintaining the ‘social self’ would trigger reliable and substantial cortisol changes” (Dickerson and Kemeny, 2004). The authors concluded that the TSST is one of the few available stress protocols that satisfies the criteria of a motivated performance task that combines elements of uncontrollability and high levels of social-evaluative threat. Their results fit with earlier work by Mason, stating that whenever a situation (or a stimulus) is perceived as novel, uncontrollable, unpredictable, or ambivalent, or if the individual anticipates negative organismic or psychological consequences, the negative feedback signals from the hippocampus and other sites will be overridden, resulting in a cascade of corticotropin-releasing hormone (CRH), adrenocorticotrophic hormone (ACTH), and cortisol secretion.

Description of the TSST Protocol

The TSST is a motivated performance task consisting of a brief preparation period (3 min) followed by a test period in which the subject has to deliver a free speech (5 min) and perform mental arithmetic (5 min) in front of an audience. The total exposure time adds up to 13 min. The following description of the TSST procedure primarily applies to investigations of HPA axis responses, and, therefore, other outcome measures may require some modifications.

The test onset should be preceded by a rest period of at least 45 min to minimize unrelated short-term

effects on the outcome measures. The subject is asked to take over the role of a job applicant who is invited for a personal interview with the company’s staff managers (selection committee). The selection panel members are introduced as being specially trained to monitor nonverbal behavior, and subjects are informed to expect tape and video recordings for later analysis of their performance. The selection committee is composed of two or three male and female collaborators of the experimenter, unacquainted with the subject. The committee is trained to communicate with the subject in an unresponsive neutral manner and does not respond with any facial or verbal feedback (note: no harassment or anger induction). The committee first requests that the subject sit down (not if blood pressure is measured) at a small table equipped with paper and pencil to prepare the talk (preparation period). After 3 min, the subject is asked to step forward to a marked spot in front of the microphone about 1–3 m apart from the committee’s table and to start the oral presentation (note: the use of written concept is not allowed). Whenever a subject finishes the speech in less than 5 min, the managers respond in a standardized way. First they tell the volunteer, “You still have some time left. Please continue.” Should the subject finish a second time before the 5 min are over, the managers are quiet for 20 s and then ask prepared questions (e.g., What are your personal strengths? What are your major shortcomings? Do you have enemies? Why? What do you think about team work?). After 5 min, the selection committee interrupts and asks the subject to serially subtract the number 17 from 2023 as fast and as accurately as possible. On every failure the subject has to restart at 2023 with one member of the committee interfering “Stop – mistake – start over at 2023, please.” After 5 min the task is terminated.

Samples are to be gained before onset and after cessation of the stress task depending on the dynamic of the selected outcome variables and should cover prestress levels, the initial stress response, peak level, and recovery. Prestress HPA axis hormone levels should not be interpreted as baseline levels since they are substantially affected by the subjects’ anticipation of the upcoming challenge. At the end of the test session the subject will be fully debriefed about the goal of the study and the nature of the stressor. A full debriefing includes a visit of the collaborators who took over the role of the selection committee.

With this protocol, salivary cortisol levels rise two- to threefold in about 70–80% of all subjects, with peak levels around 10–20 min after cessation of the stress task. In addition to free cortisol, the levels of total plasma cortisol, ACTH, catecholamines (epinephrine, norepinephrine), growth hormone, prolactin,

testosterone, systolic and diastolic blood pressure, heart rate, immune parameters (e.g., neutrophils, eosinophils, basophils, lymphocytes, interleukin-6, TNF α), glucose, α -amylase, endogenous inhibitor of monoamine oxidase (MAO-AI), as well as measures of hemoconcentration (e.g., hematocrit, haemoglobin, plasma volume) and blood coagulation (fibrinogen, von Willebrand factor antigen, D-dimer, clotting factors) increase significantly.

The TSST protocol can also be employed to test children and older adults after changing the instructions slightly for the respective age group. In elderly adults, subjects are instructed to apply for a (voluntary) part-time job (e.g., child caring, housekeeping, technical assistant). To help a retired subject take over the role of a job applicant, a fabricated newspaper advertisement can be presented (tested age range 59–91 years). The adapted TSST for children (TSST-C) also consists of a preparation period, public speaking, and mental arithmetic task. In the speaking part, children receive the beginning of a story and are told that they should finish telling the story, making it as exciting as possible, in front of a jury (tested age range: 7–14 years). The numbers of the mental arithmetic task are adapted to the performance level of the respective age group.

Although areas under the response curve (AUCs) are much higher in the morning due to the circadian rhythm of HPA axis activity, comparable free cortisol net increases after TSST exposure can be assessed with equal reliability in the morning and afternoon. However, in early morning sessions the experimenter should ensure that the onset of a stress experiment does not interfere with the morning cortisol awakening rise (CAR). Also, the appropriate time window for test sessions in the morning is smaller than in the late afternoon.

Overview of Sources of Intra- and Interindividual Differences

This section summarizes findings from studies investigating various factors that potentially contribute to differences in HPA axis responses to the TSST. One of the most prominent features of HPA axis (and other system) responses after psychological stress is the large variation in response magnitude among subjects and across test sessions. Significant differences can be observed with respect to the net hormone output as well as the time course of hormone secretion. Considerable evidence has accumulated for a significant impact of a variety of moderating and intervening variables, which are briefly summarized in the following.

Gender and Sex Steroids

One of the most consistent findings from employing the TSST is the significantly larger salivary cortisol and ACTH response (up to twice as high) in men compared to women, while prestress levels are not considerably different. The same sex effect emerges for elderly subjects (see also below). The observed sex differences point to a possible impact of female sex steroids as potential mediators of HPA axis responses to psychosocial stress. In a study of 81 healthy young adults, the TSST was applied to men, women in the follicular phase of the menstrual cycle, women in the luteal phase, and women using oral contraceptives. The results disclosed that significant sex differences emerge for ACTH and free salivary cortisol but not for total plasma cortisol stress responses. Moreover, ACTH responses were elevated in men compared to women, regardless of menstrual cycle phase or use of oral contraceptives. Women in the luteal phase had saliva cortisol stress responses comparable to men, whereas women in the follicular phase or women taking oral contraceptives showed significantly lower free cortisol responses. These observations point to the necessity of strictly distinguishing between the total cortisol secretion and the levels of bioavailable free cortisol. Whereas many animal studies can be cited that have directly investigated the impact of estrogens on HPA axis regulation, few experimental studies have been conducted in humans, and the empirical evidence is rather inconsistent.

Age

A recent reanalysis of five independent TSST studies based on 102 healthy subjects between 9 and 76 years showed that the stress task induced significant HPA axis responses in all age groups in both males and females. The data revealed no sex differences in free cortisol responses in children and younger adults, but larger free cortisol responses in elderly men than in elderly women. This effect did not appear to be attributable to self-reported stress level differences. For total plasma cortisol, elderly women showed generally enhanced cortisol response levels compared to elderly and younger men as well as younger women. For ACTH, the response was higher in younger adults, primarily due to an elevated response in younger men.

With respect to autonomic responses, differential heart rate responses and recovery after exposure to the TSST were observed in healthy children, younger adults, and elderly adults. Aggregated data across the five studies showed that there was a marked age effect in the heart rate stress response, with children and younger adults showing significantly higher increases

than elderly persons. This effect is probably caused by well-known age-related alterations in heart rate regulation. The analysis of sex effects showed that girls had higher heart rate increases during the stress exposure than boys. In younger adults, stress responses were also higher in women. Peak heart rate responses were comparable in older men and women, with only men returning to prestressor baselines during the observation period.

Lactation and Breastfeeding

Lactation in women, in contrast to rats, does not result in a general restraint of HPA axis responses to a psychosocial stressor such as the TSST. Rather, suckling seems to exert a short-term suppression of the cortisol response to psychosocial stress.

Nicotine, Coffee, Alcohol Consumption, and Dietary Energy Supplies

Nicotine is a potent stimulator of the HPA axis through induction of CRH release after binding to cholinergic receptors in the locus coeruleus and hypothalamus, and chronic smoking changes the HPA axis responses to stress. Blunted cortisol responses to the TSST were repeatedly observed in habitual smokers. It has also been shown that caffeine intake can activate important components of the pituitary-adrenocortical response in humans during resting states, and there is some evidence for combined stimulatory effects of caffeine and psychological stress on HPA axis responses. Relationships between alcohol and acute stress can be at least threefold: (1) alcohol intake can alter physiological responses to acute stress, (2) acute social stress can impact on subsequent net alcohol consumption in healthy social drinkers, and (3) acute HPA axis stress responses as well as effects of acute alcohol intake before the TSST can be altered in subjects with a positive family history of alcoholism. Finally, the availability of dietary energy supplies (e.g., short-term fasting, glucose availability) appears to exert important regulatory functions in pituitary-adrenal stress responses, pointing to an important role of the nutritional state.

Social Support and Social Hierarchy

Few data provide experimental support for the hypothesis that social support might attenuate the HPA axis response to acute stress; however, effects appear to be sex specific. The neuropeptide oxytocin seems to enhance the buffering effect of social support on stress responsiveness, at least in men. These results concur with data from animal research suggesting an important role of oxytocin as an underlying biological mechanism for stress-protective effects of

positive social support. Also, the position in a social hierarchy seems to be relevant for acute HPA axis stress responses. After the TSST, salivary cortisol levels highly increased in socially dominant subjects, while only a modest elevation was observed in subordinate men.

Personality Factors

It is tempting to speculate that the HPA axis response to stress is influenced, at least in part, by stable trait factors since the endocrine response to psychosocial stress can be viewed as a close interaction between situation and person variables within a given context. Interestingly, relationships between personality traits and stress responses only emerge after repeated exposures to the TSST. While novelty may mask the impact of personality on the cortisol stress response on the first exposure, differences in the ability to cope with the stressful situation may lead to different cortisol stress response patterns on subsequent stress exposures. With decreasing novelty and unpredictability, the impact of psychological trait variables increases, and a closer correlation with the endocrine parameters can emerge. Thus, a reliable investigation of associations between personality variables and cortisol stress responses appears to require repeated TSST exposure and data aggregation.

Habituation

After repeated exposure to (initially) stressful situations, a rapid habituation of HPA axis stress responses is normally observed. This has been reported consistently for the TSST. Recently, substantial interindividual variability of such habituation patterns was documented in a large study sample. While 52% of subjects showed the well-known HPA axis response habituation, almost 16% of the participants showed a response sensitization across three test sessions. Interestingly, altered HPA axis response habituation to TSST exposures seems to be associated with vital exhaustion, pointing to a potential mechanism for how exhaustion relates to increased disease vulnerability. However, it can be speculated that habituation might be rather specific for HPA axis parameters since TSST studies investigating stress-related changes in parameters of the sympathetic nervous system, blood coagulation indices, hemoconcentration, blood cells, or interleukin-6 (IL-6) levels did not report on habituation effects.

Interventions

First evidence shows that brief group-based cognitive-behavioral stress management training can reduce neuroendocrine or cardiovascular TSST stress

responses. It may thus be speculated that such interventions may prove useful in preventing detrimental stress effects in healthy subjects as well as patients. Other relaxation techniques (muscle relaxation, relaxing music) might also alter stress responses or facilitate recovery from TSST stress exposure.

Genetic Factors: Heritability and Polymorphisms

In addition to behavioral and situational variation, HPA axis activity appears to be profoundly influenced by genetic factors, as shown in quantitative genetic studies (family and twin studies) as well as candidate gene studies on polymorphisms in the genes coding for the glucocorticoid receptor, the mineralocorticoid receptor, the melanocortin-2 (ACTH) receptor, the melanocortin-4 receptor, the μ -opioid receptor, the GABA_A (gamma-aminobutyric-acid_A) receptor, the α -adrenergic receptor, the 5-HT_{2A} (serotonin_{2A}) receptor, COMT (catechol-O-methyltransferase), TNF α (tumor necrosis factor α), and ACE (angiotensin-I converting enzyme).

TSST and Cellular Mechanisms

In a series of experiments applying the TSST stress protocol, Rohleder and co-workers investigated the influence of age, sex, and sex hormone status on glucocorticoid (GC) sensitivity of peripheral leukocytes since a cell's response to cortisol is predominantly determined by both the steroid level it is exposed to and its sensitivity for glucocorticoids, that is, the efficacy of glucocorticoid-mediated signal transduction.

Bierhaus et al. employed the TSST to elucidate how neuroendocrine stress responses can mediate cellular processes, which, in the long run, can promote vascular diseases. Their data provide convincing evidence that the activation of the transcription factor NF- κ B (nuclear factor- κ B), a protein that is sensitive to psychosocial stress, might represent a norepinephrine-dependent pathway converting psychosocial stress into cellular dysfunction.

The TSST in Clinical Populations

In addition to healthy study participants, the TSST can be used in clinical populations ranging from psychiatric diseases to somatic complaints as shown in several studies over the last few years. To date, the TSST has been successfully applied in patients suffering from, e.g., major depression, anxiety disorder, social phobia, posttraumatic stress disorder (PTSD), burnout, exhaustion, chronic fatigue syndrome, fibromyalgia, recurrent abdominal pain, chronic pelvic pain, temporomandibular dysfunction (myofascial

pain and dysfunction), functional gastrointestinal disorders (irritable bowel syndrome or non-ulcer dyspepsia), different manifestations of chronic atopy, and atopic dermatitis or chronic allergic asthma, and adults with a history of sexual or physical childhood abuse or breast cancer survivors.

Conclusions

Over more than a decade of research, the TSST has proven a useful tool in the field of basic, applied, as well as clinical psychobiological research with a wide range of psychobiological outcome variables. As well as being used in the direct study of different biological stress systems like the HPA and SAM axis or cardiovascular system, the TSST can be used to investigate biological pathways between stress and disease or to study stress-related phenomena (e.g., effects of stress on memory and cognition) and interactions between drug and stress effects. Clinical studies continue to accumulate evidence that different diseases are associated with characteristic stress response profiles. Furthermore, biological mechanisms begin to unfold that could be helpful in explaining the stress–disease association. In a next step, the challenge for researchers will be to investigate whether the TSST protocol can be applied as a diagnostic tool for the prediction of disease susceptibility and symptom severity and/or for monitoring the efficacy of interventions.

Empirical Support

Component Factors

Beyond Coronary Heart Disease

Conclusion

Glossary

Free-floating hostility

Behavior characterized by hostile vocal inflection and facial expression, ill temper, cynicism, sleeplessness, irritability, and interpersonal conflict.

Structured interview

An assessment technique involving a series of questions meant to elicit impatience, hostility, and competitiveness among those believed to have type A-defining characteristics.

Time urgency

Behavior characterized by extreme haste, punctuality, time monitoring, and tendencies to engage in polyphasic activities with poor recall of events.

Type A behavior

“An action-emotion complex that can be observed in any person who is aggressively involved in a chronic, incessant struggle to achieve more and more in less and less time, and if required to do so against the opposing efforts of other things and other persons” (Friedman and Rosenman, 1974: 67).

Type B behavior

A relative absence of the behavioral characteristics defined as type A.

Introduction

For centuries, observers have suggested that certain personality patterns are toxic to the heart. Early reports were based on clinical observations and, as is typical in the history of medicine, such reports were either case reports or pronouncements (in lieu of data) by respected authorities. From 1930 to 1950,

such reports were typically framed from a psychoanalytic perspective. However, shortly afterward, a new conceptualization emerged. The investigators claimed to have recognized a coronary-prone personality pattern but chose to label it in a value-neutral fashion as type A behavior pattern.

Historical Perspective

Few health-related psychological constructs have received the scientific interest and widespread public recognition of the type A personality classification. Scientific interest in type A and its relation to coronary heart disease began in the 1960s with a research team at the Mount Zion Hospital in San Francisco, California. Meyer Friedman, Ray Rosenman, and colleagues identified a constellation of personality traits that were observed disproportionately among their patients presenting with coronary heart disease (CHD). These traits (labeled type A or coronary-prone) included excessive drive, time urgency, ambition, impatience, aggressiveness, hostility, and competitiveness. When confronted with stressful situations, type A individuals were believed to react with rapid, explosive retorts and increased muscle tension. These behaviors were thought to cause heightened or excessive wear on the cardiovascular system and thereby increase the risk of CHD. The relative absence of these traits defined type B or non-coronary-prone behavior.

Clinical reports suggesting a coronary-prone behavior pattern led to a multitude of epidemiological and experimental studies in the 1970s and 1980s to examine these relationships in the general population and to elucidate biological mechanisms. Assessment techniques were developed, including structured interviews, self-report questionnaires, and behavioral observations. Studies examined the relationship of type A to CHD incidence, angina, myocardial infarction (MI), atherosclerosis, and cardiovascular reactivity. Early epidemiologic studies supported an association between type A and CHD, and this led to a 1981 consensus statement by the Review Panel on Coronary-Prone Behavior and Coronary Heart Disease (organized by the National Heart, Lung, and Blood Institute) listing type A as a viable risk factor for heart disease.

Despite the early support for type A, a proliferation of research in the 1980s failed to replicate earlier findings, and several related psychological constructs (hostility, anger, and aggression) emerged as stronger predictors of CHD. As a result, interest in type A has waned in recent years. By the late 1980s, two

meta-analyses concluded that the accumulated empirical studies were inconsistent and that prospective evidence linking type A to CHD was weak. Since that time, behavioral CHD research has emphasized hostility and other related constructs over the global type A characterization. However, originators of the type A concept continue to defend its role as a CHD risk factor, blaming poor assessment techniques and a substantial drift from its original conceptualization for the discrepant research findings.

As late as the 1990s, interest in the health implications of type A behavior continued, albeit in a more limited scope. Meyer Friedman and his colleagues at the University of California, San Francisco, continued to refine clinical assessment techniques and develop interventions for reducing type A behavior. Others sought to examine type A behavior with respect to other psychosomatic health problems. Today, there is declining research interest in type A as a behavioral health risk. **Figure 1** illustrates the rapid rise and fall of this construct as a title word in psychological research publications over the past 40 years. Nevertheless, type A has served as an important catalyst for the explosion of scientific and public interest in behavioral factors associated with health, especially cardiovascular disease.

Conceptualization and Assessment

Considerable conceptual confusion has surrounded the type A construct. Type A behavior has been variously described as a medical disorder, an inappropriate coping mechanism, a strong need for productivity, or a pattern of physiological reactivity. Although most research has presumed type A behavior constitutes an enduring personality trait, other studies have

attributed type A behavior to specific cognitions that can be modified through therapeutic interventions. Much of the accumulated discrepancy in results between studies of type A may be attributable to poor agreement in construct definition and assessment.

Type A behavior was first assessed through clinical ratings applied to structured interviews or videotaped structured interviews, and these interview techniques have been further updated and expanded by Meyer Friedman and colleagues. The current technique combines both observations and subjective reporting of patients using eliciting remarks. The interview consists of multiple queries that are designed to elicit manifestation of time urgency and free-floating hostility that emerge for type A, but not for type B, individuals. Questions include “Do you mind very much waiting in grocery checkout, bank, or theater lines or waiting to be seated in a restaurant?” (time urgency) and “Do you often find it difficult to fall asleep or to continue to sleep because you are upset about something a person has done?” (hostility). Scoring is based on both endorsements of items and the presence of psychomotor signs. For time urgency, signs include aspects of facial tension, posture, speech, breathing, and perspiration. For free-floating hostility, these include facial expression, eyelid movement, vocal orientation, and hand clenching. For each item, scores are clinical ratings varying in assigned weights and ranges. Total scores range from 0 to 480, and a total score greater than 45 indicates the presence of type A traits.

As an alternative to the interview technique, self-report measures of type A were developed to simplify data collection for use in large-scale epidemiological studies of CHD. One of the earliest and most frequently used questionnaires is the Jenkins Activity Scale (JAS). Other pen-and-paper measures of type A behavior include the Framingham Type A Scale, the Bortner Scale, the MMPI-2 Type A Scale, the Gough Adjective Checklist, the Thurstone Activity Checklist, the Coronary Prone Attitudes Scale, and the Ketterer Stress Symptoms Frequency Checklist.

The content and emphasis of type A self-report measures vary substantially. The JAS includes subscales of hard-driving competitiveness, speed and impatience, and job involvement. The Framingham Type A Scale includes time urgency, competitive drive, and perceived job pressures, but does not include hostility. The Bortner scale contains 14 adjective pairs between which respondents mark the level of agreement with either type A or type B traits (e.g., “Never late” versus “Casual about appointments”). The MMPI-2 Type A Scale includes 19 items that assess the type A components of hostility, competitiveness, and time urgency; these were selected from the

Figure 1 Type A journal title citations.

total pool of MMPI-2 questions by expert consensus and verified using empirical tests of item-to-type A group classification. The Ketterer Scale compares self-ratings of type A characteristics with parallel ratings of a friend or family member.

The reliability of the various interview and self-report measures is quite good. For example, interrater correspondence for discriminating type A and B individuals using the videotaped structured interview has ranged from 75 to 90%. For the MMPI-2 Type A Scale, test-retest reliability is high ($r = 0.82$), and internal consistency is moderately high ($\alpha = 0.72$), at least for male respondents. Other self-report measures of type A show similar levels of reliability. Prevalence estimates of type A behavior have varied from 50 to 75% depending on the populations studied and assessment techniques employed.

The validity of self-report measures of type A were originally documented by comparing scores between type A and type B individuals already categorized using the gold-standard interview technique. Although both interview and self-report assessment techniques have good reliability, the two approaches are only modestly interrelated. For example, the JAS showed a 73% agreement with the type A interviews in a cross-validation sample of 419 men participating in the Western Collaborative Group Study. Similarly, the Bortner scale was shown to explain only 53% of the variability in type A clinical interview ratings. This has led to considerable debate as to whether self-report questionnaires of type A are a valid means of describing the same constellation of features identified by the structured interview. Studies using self-report measures have generally provided less association with cardiovascular health outcomes than have interview techniques. As a result, self-report measures of type A have been criticized for relying on the insight of respondents, restricting the range of type A traits, and being influenced by the social undesirability of many items. Because self-report measures do not involve a live interaction with the individual, these scales may not accurately assess the action-emotion complex described by the creators of the interview technique.

Empirical Support

Data on the association between type A and CHD have been inconsistent. Three early large-scale epidemiological studies supported an association between type A and CHD incidence: the Western Collaborative Group in 1975, the Framingham Heart Study in 1980, and the French-Belgian Cooperative Study Group in 1982. All three investigations found that

type A individuals had a significantly increased risk of CHD in individuals followed closely for 5–8 years. In the Western Collaborative Group study, 3200 employed men with no heart disease were followed for 8 years. Type A individuals (by structured interview) were found to have a 2.2 relative risk of CHD relative to type B individuals. The Framingham Heart Study, which included a more representative sampling of both men and women, showed relative risk ratios for white-collar men of 2.9 for total CHD, 7.3 for MI, and 1.8 for angina without MI; however, risks were substantially less for women and for blue-collar men. The French-Belgian Cooperative Heart Study followed 2811 male civil servants and factory workers for an average of 5 years. The relative risk ratio for type A men was 1.8 for total CHD. The latter two studies used self-report measures of type A.

Other subsequent epidemiological studies showed little or no relationship. For example, in the Normative Aging Study, correlations of the JAS type A score with CHD risk were not statistically significant. In a 40-year follow-up of 280 men from the 1947 Cardiovascular Disease Project at the University of Minnesota, no statistically significant association was found between the MMPI Type A Scale and CHD. In a large-scale 7-year prospective study (Multiple Risk Factor Intervention Trial, MRFIT), there was no association between type A and risk of coronary events, and this applied to both interview and self-report methods of type A classification. The type A-CHD relation has been much smaller in prospective versus cross-sectional studies, in meta-analyses synthesizing results from multiple studies, and among more diverse groups. Although many plausible explanations have been offered for differences among study results, meta-analyses and other attempts to synthesize results across studies have failed to provide consistent support for type A as a unique and valid predictor of CHD.

The generalizability of initial research linking type A to CHD has also been criticized because early studies were limited to middle-aged, working, White American males. Among more diverse populations, associations between type A and CHD have been weaker or nonexistent. Studies of both type A and hostility in Japan, for example, have shown little association with CHD. Instead, a type C behavior pattern, characterized by a job-centered lifestyle and social dominance at work, was predictive of CHD in working Japanese men. The type A construct may not apply for women due to the greater social unacceptability of type A traits for women.

Intervening biological mechanisms to explain the type A-CHD association have focused primarily on

the hyperreactivity of the cardiovascular and neuroendocrine systems; however, results have been inconsistent. Quantitative reviews have suggested some heightened reactivity in systolic blood pressure response and catecholamine response, but results vary by gender, type A-assessment technique, and the nature of laboratory stressors. Ambulatory blood pressure studies have also indicated some relationship between type A and cardiovascular reactivity. Type A scores have been related to the actual extent of coronary artery atherosclerosis, as judged from cardiac catheterization. Here again, initial studies were positive, but subsequent studies failed to reveal such links.

Other studies have included type A as a potential mediator of health behavior. For example, type A individuals underestimate their degree of physical exertion in response to exercise. They also work longer and at greater intensity when given a self-selected work-pace task. This may explain some of the relationships between type A and cardiovascular health outcomes such as recurrent MI or unexplained cases of sudden death.

Despite the huge accumulated literature on type A, hostility, and CHD, interventions targeting type A behavior are rare. One exception is a 14-month type A counseling approach developed at Mount Zion Hospital purportedly to change belief systems, engage in exercises to modify a sense of time urgency or free-floating hostility, and increase perceptions of personal security. This intervention has been reported to reduce the frequency of silent myocardial ischemia; however, the studies have been performed on small nonrepresentative samples of post-MI coronary patients. It is not known which therapeutic techniques included in this broad-based intervention were most effective.

Component Factors

Because the interview assessment of type A included a number of signs and symptoms, researchers became interested in the specific component factors that might contribute to CHD risk and whether type A was unique in this respect compared with other personality variables. These investigations ultimately led to a shift in the focus of CHD behavioral studies away from the type A global constellation of symptoms. When the total score and subscale scores of the JAS were contrasted, the hard-driving competitiveness factor was more strongly associated with cardiovascular disease than was speed and impatience, job involvement, or the overall type A score. Other studies showed support for hostility as the key underlying component. For example, of 12 behavioral characteristics extracted from the structured interview,

a reanalysis of the Western Collaborative Group Study data showed that the hostility component alone accounted for all of the variance explained by type A.

In their 1987 meta-analysis, Booth-Kewley and Friedman identified 18 overlapping personality variables from various assessment measures for the purposes of comparing relative strengths of association. These included global type A scores; subscale measures of speed and impatience, job involvement, hard-driving competitiveness, and time urgency; and non-type A measures of anger, hostility, aggression, depression, extraversion, and anxiety. These analyses showed that depression was more strongly associated with CHD than was type A, and CHD correlations with hostility, aggression, and extraversion were of a similar magnitude to type A. This meta-analysis and subsequent studies ultimately led to the conclusion that only the type A components related to anger, hostility, and aggression were responsible for increased CHD risk. In particular, hostility, which had long been suspected as a risk factor for CHD, was found to explain nearly all the shared variance between type A and CHD.

Today, the expanding interest in hostility as a predictor of CHD has eclipsed the original global type A as a potential risk factor. However, conceptual and assessment controversies continue as various components of hostility are hypothesized to underlie associations with CHD. Cynical hostility, as measured by the Cook-Medley scale of the MMPI, was shown to predict a fivefold increase in CHD risk in a 25-year follow-up of 255 medical students. Suppressed anger was associated with a twofold increase in mortality among 696 Michigan residents followed over 12 years. Studies linking hostility to CHD have shown associations with angiographically documented CHD. However, their cross-sectional nature precludes definitive conclusions regarding cause and effect. Prospective studies with 5- to 25-year follow-ups have shown associations between hostility and later CHD development, but similar associations exist with all-cause mortality. Therefore, the specificity of hostility with regard to CHD remains unclear.

Beyond Coronary Heart Disease

Although the focus of type A research has been primarily on CHD, hypertension, and related cardiovascular health outcomes, several studies have examined the impacts of type A behaviors in the context of entirely different medical conditions. These have included chronic fatigue syndrome, irritable bowel syndrome, and other health problems thought to involve

psychological risk factors. These studies have generated no consistent pattern of findings that implicate type A as a central causal factor, although it periodically emerges as a significant predictor of various health outcomes. The most common explanation for this finding is that type A behavior may play a mediating role in health behaviors (exercise, diet, smoking, etc.).

Despite the popular use of the type A label to describe the overachieving efforts of co-workers and family members, there have been relatively few studies of the interpersonal and occupational consequences of type A behavior. In cross-sectional studies, type A overlaps with other measures of personality and temperament (e.g., narcissism, optimism, and aggression), yet type A has not emerged as an independent mental health risk factor. In relation to perceptions of stress and satisfaction at work and home, the impacts of type A behavior have been inconsistent. Based on the available evidence, the type A constellation of personality traits is an uncertain predictor of social and emotional well-being.

Conclusion

Any fair-minded observer would be immediately impressed by the numerous links between behavior and coronary disease. The impact of various risk-enhancing and risk-reducing behaviors is unchallenged. Similarly, the impact of unusual life stressors in provoking a deterioration in already-existing CHD is reasonably established. It is less clear that a habitual personality or behavior pattern leads to the development of CHD. Ambiguities in recognizing that personality and defining its central features have plagued this area. Nonetheless, data do suggest some links between type A behavior and CHD. Current work focuses less on type A itself than on the quest for its toxic core, its mechanism of action, and the possibilities of intervention.

Glossary

<i>Analgesia</i>	Insensibility to painful stimuli.
<i>Corticotropin releasing hormone</i>	A hormone released from the hypothalamus which leads to secretion of cortisol from the adrenal cortex into the circulation.
<i>Dopamine</i>	A catecholamine neurotransmitter.
<i>Gastric acid</i>	Hydrochloric acid secreted by cells in the stomach.
<i>Helicobacter pylori</i> (<i>H. pylori</i>)	A gram-negative bacterium found in the majority of patients with peptic ulcer.
<i>Immuno-modulation</i>	Changes in the function of the body's immune defence system.
<i>Ischemia</i>	Localized oxygen deficit as a result of obstruction of the blood supply or vasoconstriction.
<i>Lactobacillus</i>	A bacterium found particularly in dairy produce and meat.
<i>Limbic</i>	Referring to several phylogenetically old brain structures thought to be central to emotionality and learning.
<i>Mucosa</i>	The mucous membrane lining the stomach and intestines.

<i>Pepsinogen</i>	The precursor of pepsin, found in the stomach mucosa.
<i>Peptic ulcer</i>	An ulcer involving the mucosa, submucosa, and muscular layers of the stomach, or duodenum, due in part at least to the action of gastric juices.
<i>Rumen</i>	The part of the stomach lacking acid-producing glands.
<i>Spontaneously hypertensive rats</i>	A specially bred strain of rats with high susceptibility to develop high blood pressure.
<i>Sympathetic</i>	The part of the autonomic nervous system which prepares the organism for the fight/flight response.
<i>Vagotomy</i>	Severing of the vagus nerve.
<i>Vagus nerve</i>	The tenth cranial nerve forming an important part of the parasympathetic system.

Background

Ulcerations of the stomach, typically manifested as nonpenetrating erosions of the gastric mucosa, are found following stress in many mammalian species (mice, rats, horses, primates, swine, reindeer, and dogs, among others). The condition is therefore considered to be a reflection of fundamental common psychobiological processes activated by stress. Although there are significant exceptions, most psychobiological studies have focused on the rat because of the extensive pool of knowledge of behavior and central nervous system (CNS) function in that species. The ulcerations are found in both the rumen and the glandular areas of the stomach. The former appear to be the result of food deprivation procedures, whereas the latter are sensitive to psychological factors (stress). The ulcerations are typically bleeding erosions of the superficial gastric mucosa along the

ridges of the gastric folds. Prolonged application of the stressor may cause full-blown ulcers, with the erosions reaching through the muscularis mucosa. Given a respite from the stressor and other potential ulcerogenic factors, however, the ulcerations typically heal within a few days.

Controversy surrounds the homologous condition in humans. Earlier, gastric ulcerations in rodents and monkeys were used as models of peptic ulcer in humans, even though the location of ulcer in humans is more typically the duodenum. Later, gastric ulcerations were regarded as homologous to the acute stress ulcers seen after burn injuries or traumatic surgery in humans. Since the discovery of the role of *Helicobacter pylori* in peptic ulcers in humans, it has been surmised that ulcerations in animals are homologous to the erosive prepyloric changes of the gastric mucosa reported in subgroups of patients diagnosed with functional dyspepsia. However, there is much more to the story.

Psychological Influences on Development of Ulceration

In the wild, ulcerations are observed in animals (both rodents and primates) following social defeat. In both wild and domestic animals, ulcerations have been reported in connection with the stress of transport and confinement. In the laboratory, ulcerations are produced by a wide variety of stressors in animals – electric shock, restraint, cold, activity stress, social stress, or combinations of these – with the purpose of exploring the role of psychological factors that may modulate the incidence and/or severity of the mucosal injury. Consciousness is a modulating, if not necessary, condition for the development of ulcerations.

Ulcerations played a key role in Selye's description of the general adaptation syndrome and constituted one of the elements of this nonspecific response to diverse noxious agents, together with shrinkage of the thymus and enlargement of the adrenal glands.

Acute Effects

To identify the psychological factors in ulceration (and other stress-related phenomena), many have employed the triadic design. Animals are tested in triplets. One animal (the executive) is subjected to a physical stressor (most commonly electric shock) that can be escaped from or avoided by instrumental responses. The second (yoked) animal is wired to the first such that the same physical stress is experienced but there is no possibility of avoidance or escape. The third (control) animal is subjected to the same apparatus conditions as the first two but not to the

stressor. By comparing the amount of ulceration between the first two animals, the psychological and physical components of the stressor can be identified.

The Executive Monkey studies with monkeys, by Brady and his colleagues, were based on a triadic design, and indicated that the executive was more vulnerable to ulceration than its yoked partner. These results were widely accepted at the time, but their interpretation was later questioned. In contrast to the Brady results, Weiss reported that executive rats developed less ulceration than their yoked partners. These inconsistencies between the monkey and rat results have been attributed to the particular group-assignment procedures and experimental parameters used by Brady rather than to species differences.

Later, Weiss demonstrated that ulceration in rats was attenuated by providing the animals with predictability for shock and was exacerbated by either increasing the response requirements (effort) required to maintain instrumental control or by introducing a component of psychological conflict. Weiss's model predicts ulceration as a function of the effort required to maintain instrumental control over a stressor and an inverse function of the feedback provided by such control. Successful coping behaviors (high feedback) ameliorate ulceration, but greater workload (effort) will increase ulceration. This model has played an important role in the development of recent theories concerning the relationships among stress, coping, and ill health in humans. Between- and within-strain studies have led to the notion that more emotional animals are more vulnerable to ulcerations than less emotional conspecifics. For example, spontaneously hypertensive rats are less vulnerable than the more emotional Wistar-Kyoto strain. Potential biological markers for vulnerability to ulceration include plasma levels of pepsinogen (also in humans) and dopaminergic function. Genetic factors certainly play a role in vulnerability to ulceration, but these are modulated by early life experiences and previous experiences of coping/noncoping, which also modulate dopaminergic function.

Proactive Effects

A number of experimenters have investigated proactive effects of one or more stressor exposures on vulnerability to ulceration under later exposure to either the same or a different stressor. Rats previously subjected to the stress of whole-body restraint generally develop less ulceration under later restraint, whereas previous exposure to an activity wheel primes the animal for later activity-stress ulceration. Using heterogeneous stress experiences, rats subjected to the same shock stress parameters that are used to induce learned helplessness (a putative model for

human depression) develop greater amounts of ulceration under a later radically different type of stressor, restraint in water. This phenomenon is mediated by opioid mechanisms in the same way that stress-induced analgesia and stress-induced immunomodulation are also invoked by these same shock parameters. Previous experience with escapable shock, on the other hand, has proactive protective effects against later ulceration, although the mechanisms of this phenomenon remain unexplored. More recent studies have complemented these earlier reports in showing that prior experience with seminaturalistic coping responses is protective against later ulcerogenesis. Similarly, prior experience with uncontrollable shocks, but in which safety signals are provided at the end of each shock, also reduces vulnerability under later stress.

Early weaning of rats (at day 16) leads to a drastic increase in vulnerability to ulceration during a limited period later on (22–40 days). Although later studies indicated that this effect was due more to nutritional and thermoregulatory influences than to psychobiological phenomena, recent reports suggest that such very early manipulations have profound long-term effects on dopaminergic system function, which is known to play an important role in ulceration.

Mechanisms

Peripheral Mechanisms

The peripheral mechanisms of ulceration were originally believed to be limited to increased levels of vagally mediated gastric acid secretion, and vagotomy does reduce ulceration. Although the old saying “no acid – no ulcer” still holds, recent approaches have focused on combinations of changes in gastric motility, gastric blood flow, and sympathetic tone. A common view is that enhanced vagally mediated acid secretion and reduced gastric blood flow represent key aggressive factors, whereas the protective factors include prostaglandin-mediated secretion of mucous, secretion of bicarbonate, and maintenance of an adequate blood supply.

The development of ulceration appears to be greatest in the period immediately following an acute stress. This has led to the concept of ulceration as a poststress or rebound phenomenon, whereby gastric acid secretion is inhibited during the application of a strong stressor (although certain stressors may increase secretion). A concurrent strong sympathetically mediated constriction of the mucosal blood vessels increases the risk for local ischemia, and slow rhythmic contractions may cause further physical damage. On release from the inhibitory (sympathetic) influence of

the acute stressor, gastric acid levels are rapidly elevated, leaving a vulnerable mucosa open to damage.

Interactions between stress and bacterial flora The role of bacterial flora is now under intensive study since the discovery that ulcer disease in humans is related to the presence of *H. pylori*. Animal psychobiological models for *Helicobacter* infection have been hindered by the fact that most behavioral studies of ulceration have been performed in rats, whereas the models for infection have largely been limited to mice, ferrets, and gerbils. It remains unclear whether bacterial flora play any part in either ulceration in animals or erosive prepyloric erosions in humans. Germ-free animals do develop stress gastric ulcerations, although to a lesser extent than normal animals, and antibiotic treatment accelerates the healing of the ulceration. From the human data, it is apparent that factors additional to *H. pylori* are involved in gastric pathology, and it remains to be clarified to what extent stress, either alone or in combination with bacterial factors, is involved. Recent results also suggest that the relationship between the bacterial population of gut and ulceration is two way: The induction of ulceration in animals by the direct application of acetic acid to the stomach lining dramatically changes the predominant bacterial species, which then return to normal as the ulceration heals. In particular, *Lactobacillus* seems to be protective and enhances the healing process. Consistent with these animal data, a small-scale study in humans has shown that *H. pylori*, although present in all patients with duodenal ulceration with a duration greater than 6 months, was not present in patients with a shorter history, suggesting that the infection is not so much a cause as a factor producing chronicity. On the other hand, a recent study of patients admitted to intensive care units shows that *H. pylori* infection was more frequent in patients exhibiting upper gastrointestinal bleeding than in patients who were not bleeding. Thus, the controversy concerning the role of *H. pylori* remains unresolved.

Central and Neuroendocrine Influences

Studies of the central mechanisms of ulcerations have focused on limbic structures, in particular the amygdala (with its close association with the vagus nerve), the septum, and the hippocampus. The stimulation of the amygdala elicits ulceration, whereas lesions of the central nucleus of the amygdala attenuate their formation. The stimulation of the dorsolateral septum reduces the amount of ulceration induced by cold-restraint stress. Lesions of the hippocampus, in particular the ventral hippocampus, exacerbate

ulceration, presumably acting through the amygdala-vagal pathways.

Studies of centrally acting peptides show that corticotropin releasing hormone (CRH) has a potent protective effect when applied directly in the central amygdala. When injected peripherally, CRH protects against stress ulceration in young, but not old, rats (in old rats, the effect is exacerbatory). CRH acts through sympathetic pathways to inhibit gastric acid secretion while at the same time stimulating bicarbonate production and inhibiting slow gastric contractions. Tests of the CRH type-1 receptor antagonist antalarmin demonstrate a potent anti-ulcerogenic effect, but the glucocorticoid/progesterone antagonist RU-38486 significantly potentiates the formation of stress-induced gastric erosions. The role of the CRH system in ulcerogenesis remains unclear and peripheral corticosterone may play an important role in cytoprotection during stress.

Thyrotropin releasing hormone (TRH) acts as a potent ulcerogenic agent and is stimulated by cold. TRH promotes both gastric acid secretion and the slow gastric contractions associated with the development of ulcerations induced by cold restraint stress. The main site of action for TRH appears to be the dorsal motor nucleus of the vagus, although a number of hypothalamic nuclei and the amygdala are also implicated.

Adrenalectomy increases the incidence of ulceration, and there is little support for the earlier notion that corticosterone plays any causal role in ulcerogenesis. Rather, the events likely to activate the pathogenic mechanisms for ulceration are also the kind of events that activate the hypothalamic-pituitary-adrenal axis.

Of the centrally acting neurotransmitters, most attention has been paid to dopamine and in particular to the D1 and D2 receptors. In line with the observation that schizophrenics rarely develop ulcers, whereas untreated Parkinson's patients are at high risk, numerous studies have provided evidence that central dopamine is protective against ulceration. A more complex picture has now become apparent because results suggest that the stimulation of dopamine D1 receptors inhibits ulceration whereas stimulation of dopamine D2 receptors has a pro-ulcerogenic effect. Within-strain comparisons of rats rated as high emotional versus low emotional reveal that the former are more vulnerable to stress ulcerations than the latter, as well as having lower levels of dopamine in the amygdala. A similar difference between these two types of animal was observed with respect to ethanol-induced ulcerations. Rats differing in their sensitivity to the dopaminergic agonist apomorphine are differentially susceptible to ulcerations and recover at

different rates, and experience with shock parameters demonstrated to increase vulnerability to ulceration change their apomorphine sensitivity accordingly. Recent evidence also suggests that the dopamine content of the gastric mucosa is important in cell proliferation of the gastric mucosa. These and other data suggest that vulnerability profiles of animals to ulcerations are manifest at both the central and peripheral levels.

Future Directions

Studies on the etiology of stress gastric ulceration have become reduced in number since the experience that *H. pylori* eradication is the most effective treatment for human peptic ulcer. However, the bacterial risk factor and the effectiveness of treatment do not in themselves account for either historical or contemporary links between stress and ulcerogenesis. Recent developments in psychoneuroimmunology offer opportunities to study how host factors (including CNS-mediated immunomodulation) may interact with pathophysiological agents, both bacterial and others, in causing and maintaining gastric mucosal changes. Specifically, stress-related failures of immune defenses may provide a window of opportunity for *H. pylori* to cause problems.

Glossary

<i>Adrenocorticotrophic hormone (ACTH)</i>	A peptide secreted by the anterior pituitary gland that stimulates the secretion of adrenal glucocorticoids; also called corticotropin.
<i>Arginine vasopressin (AVP)</i>	A hypothalamic peptide that acts at the kidney to moderate water excretion (hence, also termed the antidiuretic hormone) and acts synergistically with CRH to stimulate ACTH release from the anterior pituitary gland.
<i>Corticotropin releasing hormone (CRH)</i>	A brain peptide that mediates the neural control of ACTH release from the anterior pituitary gland and that has also been implicated in central neural actions related to anxiety and depression.
<i>Follicle-stimulating hormone (FSH)</i>	An anterior pituitary gonadotropin responsible for stimulating the growth of ovarian follicles and the secretion of estrogen in the female and the development of sperm in the male.
<i>Glucocorticoid receptor (GR)</i>	A receptor for glucocorticoids, of which cortisol is the main type in the human.
<i>Gonadotropin-releasing hormone (GnRH)</i>	A peptide that is secreted by the hypothalamus and that mediates the neural control of pituitary gonadotropin secretion.

Growth hormone (GH)
Hypothalamic-pituitary-adrenal (HPA) axis

An anterior pituitary hormone that controls body growth and metabolism.
One of the two main neuroendocrine stress response systems.

Janus kinase (JAK)
Luteinizing hormone (LH)

A kinase with two phosphorylation sites, only one of which appears to be active.
An anterior pituitary peptide that induces ovulation and the secretion of progesterone in the female and the secretion of testosterone in the male.

Mineralocorticoid receptor (MR) mRNA

A receptor for mineralocorticoid steroid hormones, of which aldosterone is the prototype.
A molecule that transcribes the genetic code from DNA.

Signal transducer and activator of transcription 5 (STAT5)

A transcription factor implicated in cell differentiation and tumor formation.

Frequency encoding of intercellular signals is a well-accepted mode of communication between neurons. More than this, however, it is actually a common mechanism of communication across a broad range of both inter- and even intracellular moieties. Even an organism as primitive as the slime mold (*Dictyostelium discoideum*) aggregates only in response to external pulses of cAMP delivered with a periodicity

of 5 min and not to constant stimuli or frequencies greater than every 2 min.

Within mammalian systems, frequency encoding is mediated by circulating hormones as major signaling molecules, and many of these signal through the mechanisms of ultradian rhythmicity. Thus, pulsatile GnRH release is essential for maintenance of LH and FSH secretion, and the modulation of GnRH pulse frequency can produce differential LH and FSH secretion via regulation of LH β and FSH β mRNA expression. Similarly, sex differences in episodic release of growth hormone (GH) elicit significant differences in gene expression. High-amplitude GH bursts occur at intervals of 3–4 h in male rats, whereas more frequent low-amplitude pulses occur in females; these sexually diergic patterns are responsible for marked differences in the expression of liver enzymes and JAK-dependent STAT5 responses.

Recent advances in our understanding of glucocorticoid receptor function suggest potential mechanisms for similar regulation of gene expression in cells exposed to pulsatile changes in glucocorticoid concentration. At the level of the glucocorticoid receptor itself, Dekelbab et al described in 2004 a rapid downregulation of GR associated with prolonged exposure to glucocorticoids that can be avoided if corticosterone is administered intermittently. This suggests a more effective induction of GR target genes from intermittent pulses of glucocorticoids. Furthermore, it is now recognized that the binding of the GR to the promoter regions of target genes is not the static process that was previously accepted. The availability of GR tagged with fluorescent tags and the advent of chromatin immunoprecipitation (ChIP) techniques have revealed that the interaction among the GR, DNA, and other proteins involved in transcription is a highly dynamic process. Indeed the effective concentration of nuclear receptors on some promoters appears to vary after hormone stimulation in a wavelike or cycling fashion. Métivier et al. described a transcriptional clock with another steroid ligand receptor – the estrogen receptor – engaging in 40-min cyclic occupation of a target promoter.

The HPA axis shows classic hormone rhythmicity. In the basal state, normal HPA activity is characterized both by a circadian rhythm of cortisol and corticosterone and also an ultradian rhythm that results in a pulsatile release of ACTH and glucocorticoids throughout the 24-h cycle. This ultradian rhythmicity is clearly a fundamental feature of HPA activity and *ex vivo* evidence from the monkey suggests that the pulse generator is located within the hypothalamus. This pulse generator results in the phasic release of CRH and AVP from the parvocellular neurons of

the hypothalamic paraventricular nucleus into the portal blood, from which it has access to pituitary corticotrophs that secrete ACTH, which in turn regulates the production and release of glucocorticoids from the fasciculata cells of the adrenal cortex.

Details of studies on the intrinsic dynamics of HPA function in free-running conscious animals reveals a complex ultradian rhythm of corticosterone secretion of approximately 1 h in duration. This profile shows not only marked sexual diergism, but also shows marked plasticity in different physiological states such as lactation and aging, the presence of or susceptibility to disease, and early life programming. Similar ultradian rhythmicity is found in humans, resulting in complex patterns of cortisol secretion that have made the response to stress testing difficult to interpret.

The rapidly changing concentrations of glucocorticoids have major potential implications with respect to the pharmacokinetics of receptor occupancy and signal transduction because, over relatively short periods of time, there are widely changing concentrations of ligand available for both MR and GR binding. Although there is little data on this, it appears likely that this is of a special relevance for GR occupancy because the high affinity of the MR suggests that short-term changes in ligand concentration have only relatively small effects on MR signal transduction.

Pulsatility provides an added dimension to the regulation of hormone responsive pathways. Not only can it provide an additional mode of signaling within the same amount of total hormone secreted, but it could also potentially have differential effects on different tissues within the same organism. This could be picked up both by different patterns of expression of the hormone receptors (e.g., MR and GR) and by differential effects on receptor recycling, postreceptor signal transduction, or interaction with other intracellular pathways.

Understimulation and Boredom as a Rustout Syndrome
Understimulation and the Stress Response
Conclusion

Glossary

<i>Boredom</i>	The state of being tired or made weary by being dull, repetitious, or uninteresting; an emotion in response to an environment that is perceived to be monotonous and that fails to stimulate the individual.
<i>Understimulation</i>	Insufficient arousal in respect to the senses or activity in the individual.

Understimulation and Boredom as a Rustout Syndrome

While a plethora of research evidence exists to suggest that overstimulation in the form of work overload is a key source of stress, associated with a wide variety of negative health and performance variables, the issue and impact of understimulation and boredom should not be ignored or underestimated. Overload as a form of stress can lead to burnout, whereas the lesser used term of rustout might be useful to explain the negative impact of understimulation that results in boredom, apathy, low morale, and absence from the workplace. It is suggested that an unvaried work environment lacks stimulation, and repeated performance of a routine task can be perceived as monotonous. For example, Persson and colleagues observed that understimulation was a potential problem associated with operator work in automated process control, where monitoring was a predominant part of the job. Such conditions can lead to rustout. Similarly, a medical practitioner might experience rustout when the individual feels that his or her skills and abilities are not being utilized to his or her satisfaction. In both instances, the workplace or job produces feelings or emotions that are described as “boring”. When an

employee feels able to produce a report but is not permitted to do so because the boss always expects to take over completion of the final document, qualitative underload is experienced. This can also be viewed as understimulation, and the perceived state of boredom or job dissatisfaction is described as the stressor outcomes or stress response. Lack of a stimulating work environment or challenge may be classified as the stressor or source of stress. These form a stress chain, namely, the stressor leads to perception of a state of stress, which leads to the stress response, or coping. However, it must be acknowledged that stress chains and cause-and-effect relationships are not simple or necessarily linear. Boredom, like pain, can not be seen or measured in an objective way because it is a subjective experience, mediated by individual differences such as personality, needs, wants, and past history. While agreement is not unanimous, it is usually acknowledged that there is an association between boredom and a state of low arousal. Grandjean placed boredom in his categories of fatigue, describing it as mental fatigue wherein the individual reports a feeling of weariness. Research evidence suggests that mentally fatigued workers are likely to behave in an inconsistent manner and/or take short cuts, thereby jeopardizing safety and performance standards. Kass and colleagues demonstrated the business costs associated with boredom at work. Workers in a manufacturing plant scoring high on both state and trait boredom were significantly more dissatisfied with the work itself, pay, promotion, supervisors, and co-workers. Those scoring high in job boredom were also more likely to be job absent, but had longer organizational tenure.

Understimulation and the Stress Response

Early research findings presented by Yerkes and Dodson explained that a certain amount of stimulation (i.e., arousal) was needed for optimal performance but that both understimulation and overstimulation could produce negative effects upon the individual in terms of poor health and ineffectiveness. Thus, the curvilinear relationship observed between level of arousal and performance outcome, known as the Yerkes–Dodson Law or the inverted-U hypothesis, clearly illustrates how too little stimulation can lead to boredom, apathy, and ultimately, depression (i.e., rustout), while overstimulation can result in high anxiety, tension, and burnout. However, response to stimulation will vary among individuals because it is a subjective experience

contingent upon one's perceptions of the experience. A tale of stonecutters in the Middle Ages provides an illustration of the role played by our perceptions in a potentially understimulating situation in the workplace. A traveler approached a group of stonecutters and asked, "What are you doing?" The first responded, "I'm cutting stone. It's dull work but it pays the bills." The second stonecutter said, "I'm the best stonecutter in the land. Look at the smoothness of this stone, how perfect the edges are." The third man pointed to a foundation several yards away and said, "I'm building a cathedral." Thus, a state of stress is said to exist when an individual perceives an imbalance between the perceived level of demand (i.e., stimulus arousal) and his or her perceived ability to meet that demand.

When the task structure or design of the job is perceived as monotonous or repetitive, it can be demotivating and a barrier to performance effectiveness. Typically, such jobs offer little scope for decision making, autonomy to influence working methods, or pace and sequence of task. The passive job described by Karasek is typically a low-demand, low-autonomy job, and as such will generally be dissatisfying as it induces a decline in overall activity and a reduction in general problem-solving activity. Indeed, Zavala and colleagues observed that workers with a low workload were late to work or left early more often than individuals with an average or high workload. However, not all research findings support the notion that industrial monotony must have negative health or poor productivity effects because expectation determines how the situation is experienced. Hence, the sameness of the job is regarded as normal, and while it might not be liked, there seems to be no expressed job dissatisfaction or harmful health effects. The job is simply viewed as an instrumental means to the ends of obtaining what the employee needs outside of the workplace. The notion of understimulation as lack of or low arousal was expanded by the work of French and Caplan, who explained the concept in terms of workload while distinguishing between quantitative and qualitative load.

Quantitative versus Qualitative Underload

It is possible to experience quantitative underload as understimulation because one simply does not have enough to do to fill the time. Cooper and Kelly reported that crane operators confined to their cab and presented with a very low level of work activity experienced quantitative underload, which was a significant predictor of anxiety, depression, and job dissatisfaction among this group of workers. Boredom in the daily routine as a result of too little to do might result in inattentiveness, which is potentially

hazardous, for example, when an employee fails to respond to an emergency situation. Dangers become exacerbated during night-shift work when an individual must adjust to a new sleep pattern but does not have enough to do to stay alert. Cheliout et al. found a high incidence of deactivation episodes among electronics assemblers who were monitored by continuous electroencephalography over a 1-day period. The theta rhythms observed, described as microsleep (i.e., asleep with one's eyes open), were indicative of the boredom and tedium experienced by these workers. When a task does not provide opportunities to use or develop skills and abilities, the situation is described as qualitative underload, and the individual can feel undervalued and bored. This state of apathy can lead to poor morale, irritation, depression, job dissatisfaction, and absenteeism. Thwarted ambition, unfulfilled goals, and unmet expectations cause frustrations that can generate various forms of destructive behavior. Examples of these maladaptive coping strategies include workplace vandalism, sabotage, alcohol and drug abuse, and binge-eating habits.

New Technology and Understimulation/Boredom

Rapid developments in computer technology and its application to industrial and commercial settings have been a major cause of stress in the workplace. A constantly changing environment is a potent stressor because employees must continually strive to keep up with new systems and methods. Technological change can bring stress in the form of social isolation, but one in which individuals are monitored. Jobs are much simplified because the computer-led process has taken over much of the hard physical effort and the decision-making process. Indeed Smith suggested that the main impact of visual display units on workplace activities was underload, de-skilling, and a lack of control. Nevertheless, the use of computers in the workplace has also resulted in responsibility being delegated further down the organizational chain than before, often without commensurate power or pay, thus causing other strains and pressures.

Conclusion

A job is boring if that job incumbent perceives it to be boring. Nevertheless, it is possible to design jobs to avoid such problems. For example, Persson et al. described this process as the design of active versus passive operator jobs, even when monitoring tasks are a predominant part of the job. To avoid problems associated with absenteeism or with employees leaving the organization in order to find a more fulfilling or stimulating job, it is possible to apply a

wide variety of human relations processes such as job enlargement, enrichment, restructuring, and rotation. As Zavala et al. suggested, the benefits are a reduction in boredom, work stress, absenteeism, and turnover and an increase in innovation, productivity, and loyalty. As such, these strategies are recommended as part of an organizational approach to stress management in the work environment.

Policy Implications

Glossary

<i>Cohort study</i>	A cohort study is one in which a group of individuals is followed over time. A birth cohort consists of a group whose members were all born at around the same time and are therefore the same age. The advantage of this for research on unemployment and health is that it allows us to see whether those who become unemployed differ in any health-relevant manner from those who do not, even before they experience unemployment.
<i>Economically active</i>	The employed and self-employed plus all those looking actively for paid employment.
<i>Economically inactive</i>	Persons who neither have a job nor are currently actively seeking one.
<i>Employment</i>	Work that either is paid by an employer or yields income from self-employment or a small business.
<i>Latent consequences of employment</i>	The idea that employment has benefits other than providing a wage, such as the opportunity to use skills, social integration, and self-esteem.
<i>Life course perspective</i>	A relatively new approach to understanding health differences between people in different social groups that takes account of experiences over time. For example, the approach looks at whether people who experience more unemployment tend to have had different experiences in childhood than those who have experienced little or no unemployment.
<i>Mac-job</i>	Employment that requires little education or training, is very low paid, and is accompanied by no career prospects, low autonomy, and low job security.
<i>Parasuicide</i>	This term does not mean attempted suicide that did not succeed, but refers to serious self-harm that is, however, not thought to be intended to result in death.

Reservation wage

Unemployment

Unemployment rate

Work

The rate of pay at which an unemployed person will consider taking on a new job. The possibility that pre-existing health may have resulted in unemployment.

Defined by the International Labour Organisation as “neither employed nor self employed and actively seeking employment.” Practices in different nations vary as to the period of time during which an individual must have looked for a job in order to be regarded as unemployed; a common usage is within the last 2 weeks. Calculated as the number of those seeking employment divided by the economically active population. Those not seeking paid work are not included in the denominator.

Not synonymous with employment. It has been calculated that at least half of the work that is done in a society is unpaid. Most unpaid work is carried out by women.

Introduction

From levels in 1977 of around 4.5% in the UK and 6.5% in the US for men over the age of 16 in the mid-1970s, the unemployment rates of these nations rose sharply to around 11–12% in the early 1980s. In the UK, unemployment rose again to another peak, over 12% in men, in the early 1990s, while in the United States it fell more steadily. [Figures 1 and 2](#) show both similarities and differences in the trends in these two nations. Although unemployment is now far lower than its highest level, conditions are very different from those of the 1970s, which preceded the 1980s recession and restructuring of labor markets. The labor market has to some extent polarized. On the one hand, there are more jobs that require high levels of education and skill in new high-technology industries and, even more, in services such as banking, law, and health care. On the other hand, the jobs available to those without further post-school education and training have increasingly become what are known as Mac-jobs (after the McDonalds catering empire). The paradigmatic Mac-job is in the fast food industry and consists of relatively unskilled forms of preparing and serving of meals. Another job typical of the new labor market is the call center. Working in a call center does not require specific qualifications or skills, but is only possible for those capable of clear, grammatical speech, without a heavy regional dialect, and who have sufficient social skills to deal with many different

(often dissatisfied) customers in a series of intensive remote encounters.

In many mainland European nations, however, large-scale replacement of unemployment by low-paid work has not yet taken place. Unemployment rates in Germany and France, for example, are still very high, at 10–11%. To some extent it could be said that mainland Europe and Scandinavia lag behind the United States and UK, in that the economic crisis of the 1980s in the latter nations occurred in mainland Europe and Scandinavia about 10 years later. It is, therefore, still relevant to consider whether there may be effects of unemployment on health.

Health Effects of Unemployment

Research has repeatedly shown a higher prevalence of ill health and excess mortality in men and women

who are unemployed. Men who are unemployed, and women who are either unemployed or keeping house full time, are more likely than those with paid employment to describe their health as generally fair or poor. Damage to psychological health is also found by the vast majority of studies, an effect that appears to be independent of pre-existing health and to be reversed on re-employment in many cases.

However, it is not a simple step from this observation to a causal relationship between unemployment and health. In aggregate level studies, increases in unemployment in nations or areas are not consistently found to be related to increases in mortality or morbidity. The increase of unemployment in industrialized nations took place during a period when life expectancy was rising steadily. This is not too great a mystery, as even what would be regarded as a very high unemployment rate would be no more than

10–15% of the economically active population of a nation. A typical rate of economic activity in an industrial nation would be 65–75% of those regarded as of working age, which is usually between around 18 and 65 years old (the rest of the population comprising children, the retired, and those looking after home and family). It is also typical of observed patterns of unemployment that the risk of job loss is not randomly spread throughout the population. In general, there will be a group characterized by having worked in a declining industry, having few skills relevant to other industries, and living in an economically declining region, who experience long-term and/or multiple spells of unemployment. This group will carry most of the total burden of unemployment for the society as a whole. This needs to be remembered when we examine the evidence on the health effects of unemployment. It is more or less impossible to find a group of workers who become and remain unemployed for any appreciable period of time who do not also suffer from one or more other burdens of socioeconomic disadvantage.

The reason we need to be cautious about studies showing that people who report that they are unemployed also report worse mental or physical health is that those who are ill may be more likely to lose their jobs and find it harder to regain employment. Or there may be indirect effects whereby men and women with other characteristics such as lower levels of education, which are known to be related to health risks, are also less likely to be employed. This type of relationship, in which certain people are more at risk of both unemployment and ill health is known as selection.

Selection

There are very few studies that have examined relationships of unemployment to health over a long time period. Convincing evidence of a causal effect would be present if long-term studies showed that healthy people who became unemployed subsequently experienced a deterioration in their health. Early studies of unemployed people in the 1970s and 1980s indicated that their physical health did not necessarily decline during a spell of unemployment; a number of studies failed to find an increase in morbidity among those who were continuously unemployed for up to 18 months. However, a more recent study of a representative sample of healthy people over a period of 10 years did observe an increased risk of developing a limiting illness in the year after having become unemployed. Another careful study carried out by occupational health specialists measured a clear deterioration in physical working capacity after a year of unemployment.

However, because of the scarcity of good long-term evidence on the health of people who become unemployed, we need to consider the possibility of what is called a selection effect. A direct health selection effect is thought to be at work when it is poorer health itself that increases the risk of unemployment. Ill health may be a risk for both initial job loss and subsequent chances of re-employment. However, studies in which an entire workplace closes down and all workers are dismissed so that there is no possibility for job loss to be affected by health have also shown increases in illness in those made redundant. Research using linked census-based data from England and Wales and from the Nordic countries has shown that higher risk of mortality is not only present among unemployed people who were already ill. A recent study in Sweden has also found excess risk of mortality among twin siblings who experienced unemployment when compared to their siblings who did not.

Although most studies of increases in national or regional unemployment do not find that these are followed by deteriorations in population health, there is most certainly no evidence that increases in unemployment happen because people's health gets worse. The large increases in unemployment during the 1980s in the Anglo-Saxon nations and during the 1990s in many European nations were not due to worsening health of workers in these countries (indeed, this will seem rather an absurd statement to make). In fact, unemployment rates increased dramatically in different nations during the 1980s and 1990s, at the same time that levels of health in the population actually improved. So there is no possibility that an increase in unemployment overall can be blamed on some kind of general deterioration in the health of the working-age population.

There may still be some tendency for those who remain unemployed for longer periods to be different from those who do not, even if this difference does not take the form of a life-threatening disease. Perhaps people at high risk of unemployment may also have certain personality characteristics, for example, an external locus of control or a weak coping ability. However, this is a more complex hypothesis, and is not necessarily the same as selection. These ideas have to be considered alongside other evidence on the life course accumulation of social and health disadvantage.

One study that has been able to ask the question "How far is the poor health of the unemployed due to their health before they became unemployed?" in relation to mental health is a British birth cohort study of everyone born in the second week of March 1958 and followed until the present time. Researchers

were able to use data on health and psychological development throughout the school years and young adult life, as well as complete employment histories from leaving school to age 33. These data showed that cohort members who experienced more unemployment were also more likely to have grown up in economically disadvantaged and overcrowded households. The study also addressed the possibility that the high level of psychological morbidity found in unemployed men and women might have been due to a pre-existing vulnerability to poor mental health. Even after taking into account pre-existing mental health, recent unemployment was clearly related to the onset of psychiatric symptoms severe enough to require medical care. However, when those with a prior tendency to depression were excluded from the analysis, this had the effect of strengthening the relationship between longer term accumulation of unemployment and the onset of episodes of depression and anxiety. This adds to the evidence that longer term unemployment causes deterioration in mental health in those who were previously healthy.

Mechanisms

What might be the reasons for the relationship between unemployment and health? Several have been put forward, and the following sections consider three of these: poverty, the fact that unemployment is a stressful life event, and changes in health-related behaviors at the time of unemployment.

Poverty

Low living standards are not an inevitable consequence of unemployment; this is a result of the levels at which benefits are set, which results from political decisions. During the 1980s and 1990s, levels of income replacement for the unemployed were lowered in many nations. It was argued that under conditions of increasing automation of unskilled and semi-skilled work, levels of benefits available to the unemployed exceeded the market worth of their labor, that is, the wage rate that employers were willing to pay. If the level of pay at which an unemployed person will accept new employment – the reservation wage – is too high, employers will not take them on. If benefit levels are too high, the state is raising the reservation wage and therefore may be contributing to the problem of high unemployment.

On becoming unemployed, most people will experience a decrease in income. The extent of this decrease varies between nations, from around 20% in some Nordic countries to approximately 60–70% or more in the UK and United States. Many studies link the health effects of unemployment directly to

financial problems. In modern welfare states, state benefits available to those unable to undertake paid employment are thought to avoid starvation and severe physical privation. However, recent research on the financial cost of what medical evidence has shown to be a healthy lifestyle, which includes a diet adequate in essential nutrients, warm housing, and a level of social participation consistent with mental health, costs approximately double the level of social security benefit in the UK. It is therefore inevitable that once savings are exhausted, unemployed people will be forced to borrow money in order to sustain health. Debt, in its turn, has been shown to increase the risk to mental health and the risk of stress-related deterioration in physical health. In several studies, long-term unemployed people who had gone into debt or had to borrow money in the past year had a risk of depression that was more than double that of those who did not have to borrow money. These studies also found that those obliged to borrow were also more likely to report deterioration in physical health. Others have documented the ways in which increasing financial pressures, as savings are used up and worn-out items need to be replaced, are responsible for the growing inactivity and social isolation of many unemployed people.

These British findings are echoed in other countries, such as the United States and the Netherlands, where financial problems were shown to be the main reason why unemployed people's mental and physical health were worse than that of the employed. However, it seems that eventually many of the unemployed adapt to straitened financial and social circumstances. Several studies agree that there appears to be no further deterioration in psychological well-being after a period of between 1 year and 18 months (but no improvement, either, so that unemployed people remain two to three times more likely than the employed to be in poor mental health). This adds weight to the argument for providing early assistance to those who become unemployed. Other evidence suggests that adaptation to unemployment is accompanied by lowered expectations of oneself, and perhaps by a degree of alienation and cynicism. This process has been compared to the adaptive process found in institutionalized inmates of prisons or psychiatric hospitals.

Unemployment as a Stressful Life Event

Research on the ways in which people react to job loss shows it to be a highly stressful life event, which has been characterized as a form of bereavement. International studies provide consistent evidence of the importance of stress. Many researchers have suggested that employment has a number of nonfinancial

benefits to the individual, the so-called latent consequences, and it is the loss of these that results in the threatening character of unemployment. These latent consequences of employment include giving a time structure to the day, self-esteem, and the respect of others; physical and mental activity; use of skills; and interpersonal contact. It may be that the loss of these psychosocial benefits of employment is at least as important as loss of income to the health of unemployed people.

Evidence of the importance of stress for the relationship between unemployment and health comes from studies in Scandinavian nations. In these nations, cash benefits to the unemployed are relatively generous, and therefore the financial effects might not be expected to be as great as in the United States or the UK; however, similar relationships between unemployment and a range of health indicators are seen. A study in Stockholm of men with irregular work histories and a variety of problems that required frequent social service assistance found that those who were employed, even in low-paid casual jobs, were all more active and integrated (and psychologically healthier) than the unemployed. Among unemployed industrial workers in Finland, those who regained paid work experienced a considerable improvement in psychological health regardless of their financial circumstances either before or after re-employment. Italian workers laid off from their jobs experienced raised amounts of both psychological and physical illness despite receiving the whole of their normal wage. These studies provide evidence of the nonfinancial benefits of employment for psychological health. Stress may affect physical health as well as psychological health as a result perhaps of chronically increased levels of anxiety and the relationship this may have to the functioning of the endocrine system.

Health-Related Behavior

There is evidence that unemployment is associated with some forms of health-damaging behavior, although previous research has yielded inconsistent findings on the relationship. Associations between unemployment and health behaviors need to be seen in the context of the longer term development of these behaviors. The little research that exists on this topic seems to indicate not so much that people who become unemployed take up new, health-damaging activities such as smoking and drinking, not least because the costs of these pursuits could be ill-afforded. Rather, it seems that the experience of unemployment makes it harder for individuals to carry through their intentions to improve their health

behaviors. For example, in one study, after taking account of adolescent health risk behaviors, even well-educated and intelligent young men who experienced 12 months of more without a job between the ages of 23 and 33 were less likely than their peers with no unemployment experience to have a healthy lifestyle in their mid-30s.

Self-destructive behavior among unemployed men has been widely investigated. In the UK and in Scandinavian nations, suicide has been found to be more likely in unemployed people. Parasuicide (attempted suicide) has also been found to be higher in unemployed men. Unemployment seems to increase the likelihood of other adverse life events and to reduce the psychological and social resources needed to cope with these. There is, for example, a higher risk of partnership and marriage breakdown among unemployed men. Many of the unemployed also lose contact with their social networks due to the stigma of their situation.

Unemployment and Health in the Life Course

Perhaps the best way to approach the study of the relationship between health and labor market status is from the perspective that unemployment and work insecurity are part of a process through which health disadvantage is accumulated over the life course. Research taking this perspective turns away from any simple opposition between selection and causation and shows that unemployment occurs as part of a much longer term sequence of events in the life of the individual. It is now becoming possible to look at these processes using cohort studies that follow individuals from childhood to middle age. We can see, for example, that those most likely to experience unemployment may also be more vulnerable to excess mortality and morbidity because of earlier experiences of other kinds of hardship and disadvantage. Their experience of unemployment itself therefore contributes to a process of accumulation of health risks. There is little research conducted along these lines. One such analysis showed that while those with disadvantaged childhoods had the highest risk of later unemployment during the recession of the 1980s, young men who had experienced over 12 months of unemployment seemed to be on a less healthy track in terms of both social and behavioral risk, even if they were from more advantaged social origins. It seems as though unemployment also tends to wipe out some of the health advantages built up over the period from childhood to young adulthood in those who had come from socially advantaged homes and done relatively well in education.

Recent longitudinal research has made it possible to understand the relationship between unemployment and health in a more dynamic way. Biological endowment and material and emotional experiences during childhood confer varying amounts of health resources or health potential to the young person. In the real world, people from less secure and advantaged backgrounds are more likely to enter occupations with more adverse working conditions and lower rates of pay. It is of no surprise, therefore, that the aging process itself is known to take place at differential rates according to the employment history of the individual, with more arduous work being associated with faster aging. The physical resources the individual brings to the labor market when he or she must look for a new job will in many cases have already been damaged by these experiences at work, even before any spell of unemployment he or she may suffer. Many of the most hazardous (and least well paid) occupations also tend to be less secure, which means that there will be some degree of coincidence between poor health and the risk of job loss, not just because of the individual's own characteristics but also because of social structure. In contrast to physical resources, psychological and social resources are more likely to be enhanced by the experiences of activity, companionship, and cooperation involved in (even hazardous) employment. Deterioration in psychological health during unemployment is therefore more immediate and visible than deteriorations in physical health, and improvement on re-employment happens quickly.

For young people, employment forms part of the process of establishing an independent identity, so that stable employment may in fact be even more important for younger than for middle-aged or older people. For many, entry into stable employment is now preceded by long periods of job insecurity. The process of identity formation is therefore far more at risk, with accompanying rises in rates of relationship breakdown, poor mental health, addiction, and accidental and self-inflicted harm. Employment is known to aid the development of secure identity and self-esteem and to facilitate the formation of stable relationships. Accordingly, as the British economy shifted from one in which there were larger numbers of stable jobs to one in which employment conditions were more insecure, British birth cohort studies showed that levels of mental health problems in those of young working age increased sharply. Although rates of major diseases of middle age have continued to decline during the period of labor market change, rates of suicide in young men have continued to rise.

Policy Implications

A growing body of international comparative research suggests that societies with higher levels of unemployment and job insecurity may actually produce different sorts of life histories in individual members than those that provide larger numbers of secure jobs. It has been all too easy to take for granted some of the effects of quasi-full employment on the wider society. When jobs were plentiful, in order to recruit and retain workers most large firms undertook extensive training, recruiting school leavers at an early age into apprenticeships. Schools therefore had far fewer restless and unmotivated youth to deal with than would otherwise have been the case, benefiting all children in the school. Internal labor markets (the availability of promotion within a firm based on experience rather than on qualifications) offered people the chance to advance in their jobs even in the absence of school qualifications, from a later starting point. Increasing numbers of firms offered occupational pensions, thus raising the living standards of the retired population at little cost to the state. As part of the McDonaldization of the labor market, the costs of training and of supporting those who are no longer able to work for payment are now increasingly being borne by the individual (the disappearance of apprenticeships and the appearance of student loans, critical illness policies, and private pensions are examples). There has also been an increase in the numbers of persons who become economically inactive, which in many countries far exceeds the increase in the numbers of those officially unemployed and seeking employment.

Increasing the number of low-paid, low-skilled Mac-jobs is often advocated as a solution to the problem of unemployment. However, the evidence on the success of such a policy is mixed, and the impact on population health has not as yet been fully investigated.

During the 1990s, new data from birth cohort studies (studies of large numbers of people all born in the same year) added a considerable amount to our understanding of why unemployment is associated with poor health. We began to see that unemployment takes place as part of a process of accumulation of disadvantage that may begin in childhood, and that a spell of unemployment often occurs as part of a more general pattern of hazardous and insecure work. The old assumptions behind the notion of a social insurance or welfare state safety net are seen to be too simple. The people most likely to fall into the net bear a heavier weight of disadvantage than those who are less likely to need its support. The idea that benefit levels for the unemployed should be set no

higher than mere subsistence, in order not to encourage voluntary unemployment, is therefore becoming discredited. On the contrary, both the taxpayer and the unemployed person (who is of course a past and potential taxpayer him- or herself) benefits more from a generous provision of both material and psychosocial support for those who find themselves without employment.

Distribution of Urocortins

Pharmacology of Urocortins

Physiological and Behavioral Effects of Urocortins

Glossary

Adrenocorticotrophic hormone (ACTH) A hormone released into systemic circulation by the anterior pituitary as part of the HPA-stress response. ACTH, or corticotropin, induces the release of glucocorticoids from the adrenal cortex.

Corticotropin-releasing factor (CRF) Isolated by Vale and colleagues in 1981, the first hypothalamic ACTH secretagogue to be identified. In addition to its hypothalamic endocrine function, extra-hypothalamic CRF is important in behavioral and autonomic stress responses.

Edinger-Westphal nucleus An oculomotor nucleus of the midbrain that has parasympathetic projections to the ciliary ganglion and descending inputs to the brain stem and spinal cord.

Hypothalamic-pituitary-adrenocortical (HPA) axis The neuroendocrine system which, during stress, amplifies a neural signal of physiological or psychological stress into a systemic, endocrine response. Hormones secreted as part of the HPA stress response cascade equip the organism to mobilize and utilize energy resources more effectively and, more generally, respond to the stressor.

Stresscopin An N-terminally extended analog of urocortin 3 that binds exclusively and with high affinity to the CRF₂ receptor.

Stresscopin-related peptide An N-terminally extended analog of urocortin 2 that binds selectively and with high affinity to the CRF₂ receptor.

Since the isolation of corticotropin-releasing factor (CRF) in 1981, three more endogenous CRF-like peptides have been identified in mammals. The first of these – urocortin 1 (Ucn 1) – was identified in 1995 for its similar primary structure and bioactivity to suckerfish urotensin I and CRF. Ucn 1 exhibited

greater affinity for and activation of type 2 CRF receptors (CRF₂) than CRF and was hypothesized to be a natural CRF₂ receptor ligand. Urocortin 2 (Ucn 2) and urocortin 3 (Ucn 3), 38-amino-acid residue peptides, were then identified in 2001 for their structural relation to both CRF and Ucn 1 and were named urocortins due to their predominant affinity for the CRF₂ receptor. Although the urocortins share sequence identity with one another and with CRF, each is phylogenetically distinct, with the CRF peptide family resulting from multiple gene duplication events. Each peptide has a unique anatomical distribution under the control of different genes. Consequently, despite a structural family resemblance, the natural functions of urocortins and CRF in stress responses *in vivo* may differ significantly.

Structure of Urocortins, CRF, and Related Peptides

The rat Ucn 1 cDNA was cloned from a rat midbrain mRNA library in 1995. The gene codes for a 122-residue prohormone that contains Ucn 1 in the C-terminus. Ucn 1 genes also have been cloned in mouse, human, hamster, sheep (*Ovis aries*), frog (*Xenopus laevis*), and capuchin monkey (*Cebus apella*) and are similar across species. The human Ucn 1 gene lies on chromosome 2 (2p23-p21) and has two exons, with the second exon comprising the coding region, like the CRF gene. The Ucn 1 promoter is regulated by several transcription factor binding sites, including a TATA box, GATA-binding sites, a C/EBP-binding site, a Brn-2 binding site, and a cyclic AMP responsive element (CRE). Upstream of the CRE site (four base pairs), the Ucn 1 promoter contains a consensus half site for glucocorticoid response elements (GREs), consistent with the finding that glucocorticoids upregulate Ucn 1 mRNA synthesis.

The cDNAs for Ucn 2 and Ucn 3 were identified from sequence homology searches of the mouse and human genomes, with the putative Ucn 2 peptide (an N-terminally shortened sequence of stresscopin-related peptide) contained in the C-terminus of a 112-amino-acid residue proprotein, and the putative Ucn 3 peptide (an N-terminally shortened sequence of stresscopin) encoded in a 161-residue precursor. The identity of the endogenous peptides derived from the Ucn 2 and Ucn 3 preproteins remains predicted, as mature peptide sequences have not been definitively isolated and sequenced. Whether a mature Ucn 2 peptide sequence is processed in humans remains uncertain because of the lack of a consensus proteolytic

Figure 1 (a) Comparison of the primary structures of mammalian CRF family peptides. Selected putative amino acid sequences for CRF and urocortins 1, 2, and 3 across human (h), murine (*Mus musculus* [m]), rat (*Rattus norvegicus* [r]), monkey (*Cebus paella* [c]), hamster (*Mesocricetus auratus* [ma]), and sheep (*Ovis aries* [o]). Boxed regions indicate CRF superfamily homology; residues in italics and marked by down arrows are shared among all the urocortins; underlined residues marked by up arrows are shared among the type 2 urocortins (Ucn 2 and Ucn 3), but not by Ucn 1. (b) The phylogenetic tree associates human and mouse Ucn 3 and Ucn 2 with pufferfish (*Takifugu rubripes* [t]) urocortin-related peptide (URP). The more distantly related lineage is composed of ovine and human CRF, human and mouse Ucn 1, frog (*Phyllomedusa sauvagei* [p]) sauvagine, and pufferfish urotensin (tUro). The scale beneath the tree reflects sequence distances. Genbank accession sequences are provided for pufferfish-derived peptides. The phylogenetic tree was adapted from Lewis et al. (2001). *Proceedings of the National Academy of Sciences USA* **98**, 7570–7575.

processing site at the C-terminus of the putative sequence. Preproteins for rat Ucn 2 and for chimpanzee and frog Ucn 3 have also been identified. The human genes for Ucn 2 and Ucn 3 lie on chromosomes 3 (3p21.3) and 10 (10p15.1), respectively. The Ucn 2 promoter contains several GREs and is positively regulated by glucocorticoids.

Ucn 1 resembles CRF in primary structure (see [Figure 1](#)) more so than it resembles Ucn 2 and Ucn 3. In contrast, Ucn 2 and Ucn 3 resemble one another more than they do CRF, a distinction, coupled with their greater CRF₂ receptor selectivity, that has led to their characterization as type 2 urocortins. An ancient gene duplication event is believed to have given rise to separate Ucn 1/CRF vs. Ucn 2/Ucn 3 lineages, with subsequent gene duplications events differentiating paralogs within each evolutionary branch (see [Figure 1](#)).

Distribution of Urocortins

Central Nervous System

Ucn 1 has a restricted, subcortical, predominantly caudal distribution in brain. The major site of brain Ucn 1

synthesis is the Edinger-Westphal nucleus (E-W), a dorsal midbrain structure known for its role in oculomotor function. The prominent synthesis of Ucn 1 in the E-W is conserved across rats, sheep, humans, and frogs. Descending Ucn 1-like immunoreactive (LI) positive fibers of possible E-W origin are observed in (1) midbrain: substantia nigra, periaqueductal gray, interpenduncular nucleus, and red nucleus; (2) caudal midbrain/rostral pons: dorsal raphe nucleus, ventral tegmentum, basilar pontine nuclei, and parabrachial nucleus; (3) medulla, including the facial, lateral reticular, and spinal trigeminal nuclei, inferior olive, and the dorsal column nuclei, nucleus of the solitary tract (NTS), and area postrema; (4) cerebellum: in the flocculus and paraflocculus as well as deep cerebellar and vestibular nuclei; and (5) spinal cord: throughout the spinal gray and, less so, in the dorsal and ventral horns. Ascending Ucn 1-LI-positive projections, possibly from the E-W, target the septal/preoptic region and, less heavily, the hypothalamus and thalamus. Validated secondary sites of brain Ucn 1 synthesis include the lateral superior olive, the supraoptic nucleus of the hypothalamus (SON), the lateral hypothalamic area, and several brain stem and spinal cord motoneuron nuclei. Ucn 1-LI is scarce in

many regions in which CRF is prominent, including the external layer of the median eminence, the hypophysiotropic, dorsal medial parvocellular subdivision of the paraventricular nucleus of the hypothalamus (PVN), basal ganglia, amygdala, hippocampus, locus coeruleus (LC), and cerebral cortex.

Ucn 2 also exhibits a restricted, subcortical expression in rodent brain. Like Ucn 1, Ucn 2 mRNA is present in the SON and magnocellular subdivision of the PVN, in brain stem motoneurons, and in the spinal cord. Unlike Ucn 1, Ucn 2 also is expressed in the arcuate nucleus of the hypothalamus and the LC. The projection targets of Ucn 2 neurons are unknown. Nonneuronal Ucn 2 expression also is present in meninges, but not glia.

Ucn 3 exhibits the most rostral, but again subcortical, distribution of the urocortins. The three main sites of forebrain Ucn 3 synthesis are (1) the median preoptic nucleus of the hypothalamus, (2) a perifornical hypothalamic region bordered laterally by the fornix and medially by the PVN, and (3) the dorsal medial amygdala. Less prominent forebrain sites of Ucn 3 synthesis include the dorsomedial hypothalamus, both magnocellular and parvocellular components of the PVN, a region dorsal to the SON, and the posterior cortical and amygdalohippocampal transition areas of the amygdala. Ucn 3-LI-positive fibers of uncertain origin project heavily to the ventromedial nucleus of the hypothalamus (VMH) and arcuate nucleus and less so to the ventral premammillary nucleus. Outside the hypothalamus, forebrain Ucn 3 fibers of uncertain origin are abundant in the lateral septum, posterior bed nucleus of stria terminalis (BNST), and the medial amygdala. The topographical distribution of Ucn 3 in the LS differs from that of Ucn 1, with the latter innervating ventral and intermediate aspects of the structure, and the former innervating dorsal aspects. Caudally, Ucn 3 cell bodies are found in the auditory complex, and scattered Ucn 3 fibers are present in the periaqueductal gray, superior and inferior colliculi, and the ventral lateral lemniscus.

Periphery

Urocortins also are distributed in the periphery. Ucn 1 expression has been observed in adipose tissue, heart, and immune tissue, including thymus, spleen, and skin. Ucn 1 also is present in the enteric nervous system of the duodenum, small intestine, and colon, as well as in testis, kidney, adrenals, pancreas, and, possibly, anterior (but not posterior) pituitary. Ucn-1-LI also has consistently been observed in parietal and oxyntic cells of the stomach. Whether this Ucn 1 is actually synthesized by gastric tissue remains uncertain,

however, as Ucn 1 is synthesized by lamina propria macrophages, components of the stomach's inflammatory mucosal immune system. Finally, Ucn 1-LI is abundant in human placenta and fetal membranes.

In humans, Ucn 2 gene expression was detected in most peripheral tissues analyzed by polymerase chain reaction analysis, with the highest levels observed in heart, lung, muscle, stomach, and adrenal and peripheral blood cells, but not skin. In the mouse, Ucn 2 gene expression was high in skeletal muscle and skin (unlike humans), moderate in lung, stomach, adrenal, ovary, brown fat, spleen, and thymus, and low in uterus, testes, kidney, white fat, and intestine. Unlike in humans, only low Ucn 2 mRNA expression is seen in murine heart. Skin, but not skeletal muscle, expression of Ucn 2 mRNA in the mouse appears to be inversely related to circulating glucocorticoid levels.

Ucn 3 gene expression is present in adipose tissue, heart, muscle, adrenal gland, and skin, albeit at levels considerably lower than those of Ucn 2. Ucn 3 also is present in thyroid, adrenals, β cells of the pancreas, spleen, and the muscularis mucosa of the gastrointestinal (GI) tract, especially in the stomach, small intestine, and colon, but not esophagus or rectum.

Pharmacology of Urocortins

Ucn 1 binds with high affinity to every mammalian CRF binding site identified to date, including the CRF₁ and CRF₂ receptor families and the CRF-binding protein (CRF-BP). This nonselectivity differs from that of the type 2 urocortins, which have selective CRF₂ affinity and less affinity for the CRF-BP. Three CRF receptor subtypes have been identified (CRF₁, CRF₂, CRF₃), two of which have been observed in mammals (CRF₁, CRF₂). CRF receptors are encoded by separate genes, share high sequence homology, and have unique tissue distributions and pharmacological affinity profiles, permitting a diversity of function. CRF receptors belong to the G-protein-coupled, seven transmembrane domain receptor (GPCR) family.

CRF₁ Receptors

The CRF₁ receptor is a class B (secretin-like) GPCR spanning 415 amino acids. Many alternatively spliced transcripts of CRF₁ have been identified in humans, rats, mice, and hamsters. However, only one of these splice variants is known to induce signal transduction in humans and rodents (CRF_{1(a)}), so the following pharmacological characterization pertains mainly to the CRF_{1(a)} isoform. Ucn 1 exhibits reversible, saturable, high-affinity binding to CRF₁ receptors

transfected in stable cell lines. Ucn 1 is two to six times more potent than CRF at binding to the CRF₁ receptor and two- to threefold more potent than CRF in stimulating the production of cAMP from CRF₁ expressing cells *in vitro*. Ucn 1's affinity for the CRF₁ receptor is determined by regions in the first three extracellular domains of the receptor. In contrast to Ucn 1, the type 2 urocortins have very low potencies to activate adenylate cyclase via CRF₁ (EC₅₀ 100 nM), and Ucn 3 shows negligible potency to stimulate ACTH release *in vitro* (1 µM), a CRF₁-mediated bioassay. The CRF₁ receptor can employ multiple signal transduction pathways when stimulated by Ucn 1. These include activation of adenylate cyclase and protein kinase A-dependent pathways, activation of phospholipase C and protein kinase C-dependent pathways, mitogen-activated protein (MAP) kinase-dependent pathways, nitric oxide production, and proximate interactions with calcium channels.

CRF₂ Receptors

CRF₂ receptors also are class B GPCRs. To date, four major CRF₂ splice variants have been identified, including membrane-bound and soluble isoforms of CRF_{2(a)} and membrane-bound CRF_{2(b)} and CRF_{2(c)} receptors. The membrane-bound CRF₂ receptors are, respectively, 411, 431, and 397 residues in length, differing only in their extracellular N-terminus, with the CRF_{2(c)} receptor observed thus far only in human limbic circuits. Unlike CRF, all urocortins bind with high affinity to membrane-bound CRF₂ receptors transfected in stable cell lines. Ucn 1 is slightly more potent than the type 2 urocortins, but is 10–40 times more potent than CRF at binding to membrane CRF₂ receptors. However, the type 2 urocortins are much more (1000-fold) selective CRF₂ agonists than Ucn 1. The CRF₂ receptor also can activate the MAP kinase pathway, with some evidence suggesting that Ucn 3 may be less efficacious than Ucn 2 and, especially, Ucn 1 at engaging this signal transduction mechanism. The soluble CRF_{2(a)} isoform was identified in mice and results from a frameshift deletion of exon 6. In contrast to membrane-bound CRF₂ receptors, the soluble CRF_{2(a)} receptor unexpectedly shows high affinity for Ucn 1 and CRF (classically, CRF₁ ligands) and low affinity for Ucn 2 and Ucn 3. Similar to the CRF-BP (see below), the soluble CRF_{2(a)} receptor may curb CRF₁ signaling by competitively sequestering ligand.

CRF-Binding Protein (CRF-BP)

The CRF-BP is a conserved 37-kDa secreted glycoprotein that binds CRF and Ucn 1 with high affinity, thereby potentially reducing their bioavailability.

Ucn 1 and CRF are approximately equipotent at binding to the CRF-BP. Ucn 1 can displace CRF from the CRF-BP (and vice versa), thereby allowing the possibility that each ligand modulates levels of free CRF receptor agonist in the brain. The region of Ucn 1 that has affinity for the CRF-BP (residues 4–28) differs from that which underlies its affinity for CRF receptors. Ucn 1 is the main natural ligand for the CRF-BP in sheep brain and dissociates from the CRF-BP more slowly than CRF. In contrast to CRF and Ucn 1, mUcn 3 does not bind with high affinity to the human or rat CRF-BP, and mUcn 2 binds with an order lower affinity than CRF or Ucn 1 to the rat CRF-BP and with negligible affinity to the human CRF-BP.

Physiological and Behavioral Effects of Urocortins

Hypothalamic-Pituitary-Adrenocortical (HPA) Axis

Although exogenous administration of Ucn 1 can potentially activate the HPA axis, it is doubtful that endogenous urocortin 1 is a physiological regulator of the HPA axis. Unlike CRF-deficient mice, Ucn 1-deficient mice exhibit normal basal and stress-induced HPA hormone levels. Similarly, unlike CRF antisera, peripheral administration of specific Ucn 1 antisera does not modify basal, stress-induced, or adrenalectomy-induced ACTH levels. Finally, unlike the distribution of CRF, Ucn 1-immunoreactive fibers are scarce in the PVN and the external layer of the median eminence under basal conditions. Unlike both CRF and Ucn 1, intravenous Ucn 2 and Ucn 3 do not increase ACTH or corticosterone secretion, consistent with the absence of CRF₂ on pituitary corticotroph cells. However, type 2 urocortins might locally modulate CRF synthesis at the hypothalamic level, because immobilization stress increases Ucn 2 and Ucn 3 mRNA in the parvocellular PVN.

Osmoregulation

Because Ucn 1 and Ucn 2 are synthesized by magnocellular neurons of the SON and because Ucn 1 fibers are present in the posterior pituitary, an osmoregulatory role for urocortins is hypothesized. Supporting this possibility, salt loading, dehydration, and hypophysectomy increase Ucn-LI in magnocellular SON and PVN neurons, and food deprivation decreases Ucn-LI in the SON. Salt loading also increases SON Ucn 1 mRNA expression. Finally, chronic osmotic stimulation increases CRF₂ mRNA levels in the SON and magnocellular PVN, potentially increasing sensitivity to local urocortin action. Collectively, the

findings support a potential endogenous role for central urocortins in the regulation of salt/water balance. Peripheral urocortins also may control body fluid homeostasis as a result of their ability to stimulate atrial natriuretic peptide (ANP) release from cardiomyocytes, again through a putative CRF₂ mechanism. ANP, present in cardiac atrial tissue, has profound effects on salt and water homeostasis, as it acutely reduces blood volume by sequestering plasma and over the longer term by promoting renal salt and water excretion.

Energy Balance

Exogenous urocortin administration promotes negative energy balance, both by increasing energy expenditure and by decreasing food intake. The distribution of the urocortins supports the hypothesis that they may physiologically regulate energy balance via actions at CRF₂ receptors, exemplified by concordant hypothalamic expression in the VMH (Ucn 3), arcuate nucleus (Ucn 2, Ucn 3), and PVN (Ucn 1, Ucn 2) and in the NTS of the caudal hindbrain (Ucn 1). Furthermore, levels of VMH CRF₂ mRNA covary with circulating leptin levels, providing a homeostatic mechanism for modulating sensitivity to catabolic urocortin action. The presence of urocortins in the GI tract, glucose-regulating organs, and adipose tissue also is consistent with a possible peripheral role for urocortins in energy balance regulation.

With respect to energy expenditure, Ucn 1 (intracerebroventricular [ICV] administration) increases whole body oxygen consumption as measured by indirect calorimetry and increases sympathetic nervous system activity. The hypothalamus is a candidate site for metabolic action for urocortins, as intra-PVN Ucn 1 increases plasma leptin levels, induces intrascapular brown adipose tissue (BAT) uncoupling protein-1 (UCP1) mRNA synthesis, and increases the relative utilization of fat as an energy substrate. Whether energy expenditure-increasing effects of Ucn 1 are mediated in part by CRF₂ receptors and shared by the type 2 urocortins is unclear.

With respect to energy intake, peripheral Ucn 1 or stresscopin administration potently reduces food intake in rodents, possibly in part by slowing gastric emptying (see below). Central infusion of urocortins also potently suppresses feeding and reduces gastric emptying, effects that were shown to be at least partly CRF₂-mediated from studies that used selective agonists (type 2 urocortins), antagonists, antisense knockdown of receptor expression, and knockout mice. Unlike CRF₁ agonists, type 2 urocortins do not produce malaise, arousal, or anxiety-like effects

at central anorectic doses in the rat. The degree to which endogenous brain urocortins produce these effects under physiological conditions remains unclear. In addition to the CRF₂-mediated urocortin anorexia, brain Ucn 1 may also reduce food intake via a separate CRF₁-dependent mechanism. Possible loci for Ucn 1-CRF₁-mediated anorexia include the dorsomedial nucleus of the hypothalamus, the parabrachial nucleus, and caudal hindbrain glucoregulatory sites.

Ucn 3 is present in pancreatic islet β cells, with pancreatic Ucn 3 levels responsive to changes in local glucose levels. Exogenous Ucn 3 administration increases glucagon and insulin levels *in vivo* and *in vitro*, resulting in a net increase in blood glucose levels. Glucoregulatory effects of Ucn 3 were abolished by pretreatment with a selective CRF₂ antagonist. Altogether, findings suggest an autocrine or paracrine regulation of glucose homeostasis by pancreatic Ucn 3.

Gastrocolonic Motility and Function

Stress also releases CRF-related peptides, possibly including urocortins, which slow gastric emptying through CRF₂ receptor systems. Through vagal efferents, central infusion of CRF receptor agonists reduce antral gastric motility, inhibit high-amplitude gastric contractions, and shift duodenal activity from fasted to fed motor patterns. Parallel to the central CRF₂ pathway for stress-induced gastric stasis, peripheral CRF₂ receptor activation delays gastric emptying, with peripheral (intravenous [IV] or intraperitoneal [IP]) administration of agonists with high (i.e., Ucn 1) or selective (i.e., Ucn 2 or Ucn 3) CRF₂ affinity delaying gastric emptying more potently than CRF. Like central infusion, peripheral Ucn 1 administration reduces antral gastric motility in fed rats and shifts gastric motor patterns from a fasted to fed state. Ucn 1 also hyperpolarizes stomach smooth muscle. Candidate regions that subserve CRF₂ receptor-mediated gastric stasis include, centrally, the PVN and dorsal vagal complex and, peripherally, myenteric fibers of the enteric nervous system. A physiological role for urocortins in stress-induced slowing of gastric emptying is supported by the presence of urocortins in the PVN, NTS of the caudal hindbrain, GI tract, and enteric nervous system.

Gastric Ucn 1 also may regulate gastric acid secretion, as peripheral administration of CRF₂ receptor agonists inhibits gastric acid secretion and increases gastric mucosal blood flow. Anatomical evidence supports such a relation. Ucn 1 colocalizes with tyrosine hydroxylase in parietal cells of the stomach, in proximity to CRF₂, but not CRF₁ receptors. CRF₂

receptors, in turn, colocalize with H⁺/K⁺-ATPase, the enzyme gastric proton pump, and somatostatin, which inhibits parietal cell activity and secretion of gastrin and histamine.

In contrast to their effects on gastric motor function, stressors stimulate colonic motility. Indicating a role for urocortin/CRF systems in these effects, central and peripheral administration of CRF₁, but not CRF₂, agonists likewise stimulates colonic motility, and selective CRF₁, but not CRF₂, antagonists attenuate stress-induced stimulation of colonic motility. Candidate substrates for CRF₁-mediated stimulation of colonic motor function include, centrally, the PVN and LC/Barrington nuclei that activate sacral parasympathetic nervous system activity and, peripherally, the colonic myenteric nervous system. Ucn 1 is expressed in these tissues, and, therefore, endogenous Ucn 1 may partly mediate the colonic-stimulating effects of stress.

Cardiovascular Function

Intravenous administration of urocortins more potently reduces blood pressure and has greater vasodilating effects than CRF. The relaxant effects of urocortin are mediated by arteriole and possibly cardiac CRF₂ receptors and appear to involve activation of protein kinase A and MAP kinase signaling pathways as well as inhibition of a PKC-dependent contractile mechanism. CRF₂-deficient mice have elevated mean arterial pressure, suggesting a physiological function of urocortin/CRF₂ interactions on vasculature *in vivo*. Independent of its effects on peripheral vascular resistance, systemic Ucn 1 infusion also had prolonged cardiac inotropic actions in sheep, increasing cardiac contractility, heart rate, and aortic blood flow.

Urocortins also are increasingly recognized to have cardioprotective and cardiovascular function-enhancing effects on compromised heart. Urocortins protect cardiac tissue from ischemia-reperfusion injury or hypoxia-reoxygenation injury via CRF₂ mechanisms. The cardioprotective effects of urocortins appear to involve activation of ERK1/2-p42, 44 signaling pathways, the phosphatidylinositol-3 (PI-3) kinase/Akt pathway, and protein kinase C epsilon isozyme activation. The cardioprotective effects also appear to involve reduced mitochondrial damage, achieved by increasing mitochondrial K_{ATP} channel opening. In addition to its cardioprotective effects, exogenous Ucn 1 also has cardiac hypertrophic effects, involving an Akt-dependent pathway.

Supporting a physiological cardioprotective role for urocortins, Ucn 1, 2, and 3 are present in the heart, with Ucn 2 and Ucn 3 abundant in myocardium.

Plasma Ucn 1-IR increases in human systolic heart failure, and Ucn 1 expression increases more than ninefold in viable human myocytes after surgical cardioplegic arrest-reperfusion. Finally, cardiac myocytes isolated from CRF₂-deficient mice are more susceptible to ischemia-reperfusion injury.

Immune Function

As described previously, urocortins are expressed in immune tissue, including thymus, spleen, and/or skin, with Ucn 1 seen at the cellular level in lymphocytes, macrophages, fibroblasts, and mast cells. Exogenous Ucn 1 administration has palliative effects on experimental autoimmune encephalomyelitis and thermal injury-induced edema (although this may reflect glucocorticoid, vasodilatory, or direct cytoprotective mechanisms, as opposed to immunomodulating mechanisms). However, converging lines of evidence suggest that immune-derived urocortins locally modulate proinflammatory responses to perceived environmental insults.

For example, Ucn 1 mRNA is expressed in lamina propria macrophages, and Ucn 1-IR is detected throughout the entire lamina propria layer of the intestine. Intestinal Ucn 1 activity may be regulated by changes in the intestinal milieu, such as passage of dietary factors or food-associated bacterial antigens. Ucn 1-IR is elevated in the intestinal lamina propria macrophages of patients with ulcerative colitis, in which it is hypothesized to have a proinflammatory CRF₁-mediated effect. Intraperitoneal administration of CRF₁ agonists, such as Ucn 1, also increases intestinal mucosal permeability to macromolecules.

Other inflammatory conditions also are accompanied by increased Ucn 1 expression. In rheumatoid arthritis (but not osteoarthritis), Ucn 1-IR and Ucn 1 mRNA are elevated in synovium, and the number of Ucn 1-positive cells in synovia, including leukocytes and macrophages, is not only higher, but also correlates with the degree of inflammation. Supporting a proinflammatory property of secreted Ucn 1, Ucn 1 stimulates proinflammatory cytokine production by peripheral blood mononuclear cells *in vitro*, presumably, like CRF, via a CRF₁-mediated mechanism.

Some stress-related dermatological inflammatory conditions also have altered urocortin/CRF signaling. Mast cells, which play a role in allergy and inflammation, are widely distributed in the skin and synthesize and secrete both CRF and Ucn 1 in response to psychosocial stress or immunoglobulin E receptor cross-linking. Mast cells also express CRF receptors, activation of which leads to the release of proinflammatory mediators. Thus, atopic dermatitis, psoriasis, and alopecia areata have been

hypothesized to involve a stress-related precipitation or exacerbation of mast cell activation via local CRF/Ucn 1–CRF receptor signaling.

The reproductive tract also contains mast cells. Ucn 1-IR is increased more than 10-fold in spontaneous abortion products from women with a history of multiple nonelective abortions relative to products from elective or nonhabitual abortions. Supporting the hypothesis that the observed increase in Ucn 1-IR is related to mast cell activation, levels of tryptase, which constitutes one-fifth of all protein in mast cells, and IL-8, an abortogenic mast cell-derived cytokine, also are robustly elevated in habitual spontaneous abortion products. Endometriosis also is associated with an increased number of activated mast cells in association with strong Ucn 1 immunostaining. Normal endometrium, in contrast, shows low tryptase and Ucn 1 immunoreactivity. Thus, Ucn 1 expression and mast cell activation are both elevated in inflammatory conditions of the reproductive tract and may correlate with increased risk for spontaneous abortion.

Finally, Ucn 1-IR is increased in stomach biopsies from patients with active gastritis. Unlike the colon, the stomach is much richer in CRF₂ than in CRF₁ receptors. As a result, in contrast to the CRF₁-mediated proinflammatory effects of intestinal Ucn 1, stomach Ucn 1 has been hypothesized, via CRF₂ receptors, to reduce/repair injury to gastric mucosa following noxious stimuli. Consistent with this perspective, Ucn 1-IR increases in treatment-responsive, but not treatment-resistant, patients during recovery from gastritis.

Reproductive Function

In addition to mast cells within the reproductive system, the human reproductive system itself expresses Ucn 1, CRF receptors, and CRF-BP. Ucn 1-IR is produced by choriodecidual and placental tissue and is elevated in maternal plasma from midgestation through birth. Placental Ucn 1 appears to act as a vasoactive relaxant factor on uteroplacental vasculature via local action at CRF receptors. Supporting the physiological relevance of this mechanism, pregnant women who have impaired uterine artery blood flow have significantly reduced circulating Ucn 1 levels in proportion to the degree of increased arterial resistance. Urocortins also may stimulate uterine contractility, as myometrium expresses both CRF₁ and CRF₂ receptors. Whereas CRF inhibits contractility via CRF₁ receptors, urocortins increase myometrial contractility via local CRF₂-mediated actions. Thus, urocortins may regulate placental vessel resistance to blood flow and stimulate uterine contractility.

Anxiety-Related Behavior

Central administration of Ucn 1, like CRF, has anxiogenic-like properties in many rodent anxiety models that are mediated at least partly by CRF₁ receptors. Ucn 1's effects on acoustic startle responding appear to differ from those of CRF, however, as exogenous Ucn 1 dampens rather than potentiates the acoustic startle response. Contrary to the effects of CRF₁ receptor agonists, ICV type 2 urocortin administration does not consistently increase anxiogenic-like behavior. For example, Ucn 3 did not increase anxiety-like behavior in the open field, elevated plus maze, light/dark box, social interaction, or defensive burying tests. Ucn 2 (ICV) similarly lacked acute anxiogenic-like effects in the rat open field and elevated plus maze tests. In fact, ICV Ucn 3 acutely produced anxiolytic-like changes in the elevated plus maze and light/dark box tests, and Ucn 2 had delayed, anxiolytic-like effects in the plus maze and reversed the anxiogenic-like effects of CRF in the open field. Similarly, whereas CRF₁ agonists increased activity in familiar environments, type 2 urocortins had mild motor suppressing effects.

However, stress-like effects of CRF₂ receptor activation also have been reported following local microinfusion into discrete brain regions, including the lateral septum and dorsal raphe, findings somewhat incongruous with the reviewed effects of ICV type 2 urocortin administration. Furthermore, unlike in rats, exogenous ICV administration of Ucn 2 to mice increased anxiety-like behavior in the plus maze as well as acoustic startle responses. Thus, although it is accepted that CRF₁ receptor activation has anxiogenic-like effects, general conclusions about the anxiety-related effects of central administration of the CRF₂-selective type 2 urocortins are not yet entirely possible and may involve brain region or species specificity. The endogenous roles of urocortins similarly remain unclear, as one Ucn 1-deficient mouse model exhibited normal anxiety-like behavior, whereas another showed increased anxiety-like responses.

Hearing

Ucn 1 may be required for normal hearing, as Ucn 1-deficient mutant mice have shorter hair cells in the inner spiral bundle of the organ of Corti and a higher response threshold in the auditory brain stem response examination than wild-type littermates. Perhaps reflecting this difference, a second murine model of Ucn 1 deficiency exhibited a reduced acoustic startle response. Anatomically supporting a relation of Ucn 1 to audition, Ucn 1-IR neurons are present in the lateral superior olive as well as in the inner spiral

bundle of the organ of Corti. In the organ of Corti, Ucn 1 appears at 8 days of age, present only in the inner hair cell region, in proximity to CRF₁ and CRF₂ receptors.

Glossary

<i>Antigen</i>	Any molecule that generates and binds to an antibody.
<i>B lymphocytes</i>	A major type of lymphocyte; when activated by antigen, B lymphocytes differentiate into cells that produce antibodies against the antigen.
<i>Immunoglobulin</i>	Immunoglobulins are secreted by B lymphocytes and help fight infection through various mechanisms; also known as antibody.
<i>In vitro techniques</i>	Experimental techniques in which the experiment is performed outside a living organism; the conditions, and therefore the results, may not represent <i>in vivo</i> function.
<i>In vivo techniques</i>	Experimental techniques in which the research is conducted within the whole organism.
<i>Neuroticism</i>	A traitlike, or stable, personality dimension consisting of emotional instability and maladjustment.
<i>Thymus-dependent antibody responses</i>	Antibody responses, usually against a protein antigen, that require that the B lymphocytes gets help from T lymphocytes.
<i>Thymus-independent antibody responses</i>	Antibody responses, against a polysaccharide or lipopolysaccharide antigen, in which the B lymphocytes do not require help from T lymphocytes.

T lymphocytes A major type of lymphocyte; one of their many functions is helping B lymphocytes produce an antibody response.

Vaccination The injection of a dead or attenuated pathogen (disease-causing agent) in order to induce an adaptive immune response and protect against disease.

Introduction

Historically, the immune system has been considered to function in a relatively autonomous manner. Many years of research, however, have now revealed that the immune system is inextricably linked with the complex neuroendocrine networks of the body. These interactions provide plausible biological pathways through which psychological factors can influence immune function.

There is now considerable evidence that periods of chronic stress are associated with reductions in the number of a variety of immune cells in peripheral blood and with the impaired function of these cells *in vitro*. However, the clinical implications of these changes in healthy people, and within normal ranges, are unclear. Changes in cell number will not necessarily result in a significant change in the capacity of the lymphoid system to make an effective response to antigenic challenge; they may just reflect changes in the dynamics of lymphocyte migration and recirculation and other factors, such as shifts in plasma volume, rather than absolute changes in total cell numbers. Similarly, it is difficult to generalize *in vitro* measures of immune function, such as lymphocyte proliferation to mitogen and natural killer cell cytotoxicity, to *in vivo* processes. The isolated testing of any particular aspect of the network of immune cells provides limited information about the status of the highly integrated, complex immune system and, as such, has limited application to overall understanding of the relationship between stress and susceptibility to disease.

In contrast, the vaccination model affords an ecologically valid means of examining the associations

between psychosocial variables and the *in vivo* response of the immune system to antigenic challenge. Significantly, this response occurs within the functional context of the neuroendocrine system. A higher antibody response to vaccination is considered to be indicative, at a general level, of a well-functioning immune system and, at a more specific level, is likely to be associated with greater protection levels against the particular disease in question. As such, the adequacy of the immune response to vaccination has direct clinical relevance, both in terms of maximizing protection following vaccination and as a model of the response to naturalistic infection.

The Vaccination Model

Basic Immunology of Vaccination

The immune response to vaccination involves the coordination of a wide variety of immune cells. The vaccine antigen is initially recognized and presented by professional antigen-presenting cells, such as dendritic cells. The antigen is then recognized by specific T lymphocytes, which proliferate and differentiate into T-helper-2-cell lymphocytes. Vaccine antigen is also recognized by B lymphocytes without the necessity for antigen processing. When stimulated by antigen, B lymphocytes proliferate and mature into short-lived plasma cells, which produce the earliest immunoglobulin, IgM. In a primary response to a previously unseen antigen, peak IgM response occurs around 5 days after vaccination. The interaction between the activated T and B lymphocytes leads to the formation of germinal centers and, therefore, the production of high-affinity IgG and IgA antibody. This response is slower than the IgM response and reaches a peak around 28 days after vaccination. Secondary antibody responses, in which the immune system has been previously exposed to the antigen, are more rapid and of greater magnitude.

Types of Vaccination

The vaccination model also allows the examination of which aspects of the immune system may be vulnerable to psychosocial influence. The antibody response to most vaccines is thymus-dependent, in which T-lymphocyte help is required for the production of antibody by B lymphocytes. In contrast, for thymus-independent antibody responses against polysaccharide antigens, B lymphocytes generate an antibody response without T-cell help. If, for example, the effects of stress are restricted to antibody responses to thymus-dependent vaccines, this would

imply that T lymphocytes are more susceptible to psychosocial influence than B lymphocytes.

Stress and Antibody Response to Vaccination

Cross-Sectional Studies

Early studies took advantage of the large number of people undergoing routine vaccination, such as meningitis C vaccination for all young adults and hepatitis B for medical students. The largest of these studies examined the association between life events stress and the final antibody titer against hepatitis B vaccination in two cohorts of students, vaccinated either in the past 12 months or at least 13 months previously. Whereas life events exposure was not related to antibody response in the recently vaccinated cohort, participants in the earlier vaccinated cohort who reported higher life events stress over the past year were over twice as likely to show an inadequate antibody titer as those in this cohort with lower life events exposure. This association withstood adjustment for variations in unhealthy behaviors (smoking, alcohol consumption, exercise, and sleep) and coping style. The results suggest that the immunogenicity of the hepatitis B vaccination may initially override any influence of psychological factors. Further, the larger number of individuals with inadequate antibody titers in the early vaccination cohort provides more power to detect effects. Nevertheless, this study implies that psychological stress may have its principal effects on the rate of deterioration of protection.

A similar study investigated the role of psychosocial variables in the response to meningitis C vaccination. This is a conjugate vaccination, in which a polysaccharide antigen is conjugated to a protein in order to generate a thymus-dependent antibody response. This is a common technique to improve the antibody response to thymus-independent antigens. Participants with high perceived stress and psychological distress levels were more likely to have low antibody levels against meningococcal C polysaccharide following the vaccination during the previous 16 months. This finding suggests that antibody responses to conjugate vaccination are also susceptible to psychosocial influences.

Prospective Studies in Elderly Populations

In the prospective studies of psychosocial influence on vaccination response, the experimenters administered the vaccines at controlled times, in order to be able to assess pre- as well as postantibody levels. This

is particularly important with common diseases, such as influenza, in which naturalistic exposure is common. In elderly populations, the caregiver-control model has been used to investigate the influence of the chronic stress of caring for a spouse with dementia on the antibody response to influenza vaccination. Two separate studies have demonstrated that spousal caregivers are less likely to achieve a fourfold increase in antibody titer at 1 month postvaccination than matched control participants. Because this is the clinical criterion of an adequate vaccination response, these effects are likely to result in increased susceptibility to infection.

One potential shortcoming of the caregiver-control model is that caregivers may differ from controls in a number of respects other than psychological stress, such as experiencing more physical strain. Significantly, it has been shown that former spousal caregivers display the same impaired antibody response to influenza vaccination as current caregivers. Although much of the physical demand of caregiving terminates with bereavement, it is reasonable to presume that the psychological stress continues. This argues that the poorer responses to vaccination observed in caregivers is the result of psychological stress rather than physical strain. Further evidence comes from a recent study in which the efficacy of the influenza vaccination was tested in a large group of elderly people living in the community. Individuals who had experienced bereavement in the previous year had significantly poorer antibody responses against one of the three influenza strains contained in the vaccination. This suggests that a variety of chronic stressors can have a detrimental effect on antibody response to the thymus-dependent influenza vaccination.

The one thymus-independent vaccination that has been examined in elderly adults is the vaccine against pneumococcus infection. Spousal caregivers were compared to former caregivers and age-matched controls. Although there were no group differences either 2 weeks or 1 month after the vaccination, the current caregivers had poorer specific antibody titers 3 and 6 months after receiving the pneumococcal vaccination than the other two groups. This suggests that caregiving impacts the rate of deterioration of protection rather than the initial response to thymus-independent vaccinations.

Prospective Studies in Young Populations

In younger populations, a common vaccine that has been used is the hepatitis B vaccination program. This consists of three separate vaccinations, administered at 0, 1, and 6 months. In one of the first studies in this area, individuals reporting higher mean perceived

stress and anxiety over the whole vaccination period, probably indicating some trait or dispositional tendency, were less likely to have developed detectable antibodies against the vaccine by the time of the second inoculation. Although it is initially unclear why stress and anxiety levels assessed some months later may be related to this seroconversion, it is likely that these questionnaires measure, to some extent, trait or dispositional tendencies to report high stress and anxiety. It seems feasible, therefore, that people who generally tend to perceive their lives as stressful have higher mean stress scores and that it is these individuals who did not seroconvert at this time. It has also been demonstrated that the immunogenicity of the vaccine is important; a pair of studies by the same investigators found a negative effect of stress on antibody response to a low-dose hepatitis B vaccine, but the full-dose vaccination did not yield any significant stress effects.

Stress and the antibody response to the influenza vaccination has also been studied in younger adults. In one study, students who did not achieve a fourfold increase in antibody titer to the A-strains of the vaccine at 5 months postvaccination reported higher stressful life event exposures, and there was also a trend for those who were unprotected at 5 weeks to report more stressful life events in the period following vaccination. In a study of the effects of daily stress and feelings of being overwhelmed during the 10 days following vaccination, higher stress ratings were associated with lower antibody titers to one of the viral strains at both 1 and 4 months following vaccination. These studies provide evidence that stressful life events both preceding and in the period immediately following vaccination can influence the antibody response.

There has been only one study in which thymus-dependent and thymus-independent vaccines have been directly compared. This study examined the associations between stressful life events and the antibody response to the thymus-dependent influenza and thymus-independent meningococcal A + C vaccinations in a sample of 57 students. Psychosocial factors were associated with the antibody response to the influenza vaccination and were not associated with the response to thymus-independent meningococcal A polysaccharide vaccine component. This provides preliminary evidence that thymus-dependent vaccinations are more susceptible to the impact of stress than thymus-independent vaccinations.

Influence of Other Psychosocial Factors on Antibody Response to Vaccination

There is increasing interest in the influence of more stable psychological characteristics on antibody

response to vaccination. An early study in young girls found that higher internalizing, a concept similar to neuroticism, and lower self-esteem were associated with lower antibody titers following rubella vaccination. This was apparent, however, only in those who did not have serological evidence of exposure to rubella prior to the vaccination and were thus exhibiting a primary vaccine response. Trait negative affect has also been negatively associated with the secondary antibody response to the second hepatitis B injection. Similarly, neuroticism has been associated with a poorer antibody response to the influenza vaccine at both 5 weeks and 5 months postvaccination.

Social support has also been demonstrated to be associated with the response to vaccination. Two separate studies have demonstrated that students who reported greater social support have better antibody responses to either hepatitis B or influenza vaccination. Further, in a study of college freshmen, loneliness and smaller social network size were associated with a poorer antibody response to the influenza vaccination. In an elderly population, although generic social support was not associated with the influenza vaccination response, being married, and particularly reporting being in a happy marriage, was beneficial. With aging, marriage may become the primary social resource that influences health, including susceptibility to infection.

Possible Mechanisms

An association between stress and antibody response to vaccination could arise from direct and/or indirect mechanisms. The most likely indirect mechanisms are changes in health behaviors, often associated with periods of stress and their subsequent physiological impact on antibody formation. Poorer antibody responses to vaccination have been observed in those who consume high levels of alcohol, in regular smokers, and in those with inadequate nutrition. In spite of these findings, some studies have failed to adequately control for health behaviors, leaving open the possibility that at least some of the observed association between stress and antibody status may be attributable to variations in unhealthy behaviors.

More direct mechanisms of interaction between stress and immune function have also been postulated. Stress is associated with alterations in sympathetic nervous system and hypothalamic-pituitary-adrenal axis activation. Functional relationships between these neuroendocrine pathways and the immune system have been acknowledged for some time, including the innervation of lymphoid tissue and

neuroendocrine receptors on many types of immune cells. Therefore, it is feasible that changes in the basal activity in these systems or their repeated activation in response to stress could impact on antibody development and maintenance.

The Possible Paradoxical Effect of Acute Stress

In contrast to the immunosuppressive effects of chronic stress discussed so far, it has also been suggested that acute stress may be immunoenhancing when experienced close to the immune challenge. Dhabhar and McEwen argued that immunoenhancement by acute stress is adaptive from an evolutionary standpoint and might be regarded as an integral component of the fight-or-flight response. From this perspective, circumstances that initiate a fight-or-flight response are likely to also involve exposure to antigens and, therefore, a robust immune response would be adaptive for survival. There is now convincing evidence from animal studies of acute stressors in close temporal proximity to vaccination that provides support for an immunoenhancing effect of stress on the antibody response. Only one study has examined the effect of acute psychological stress on antibody response to vaccination in humans. Participants completed either a 45-min time-pressured, socially evaluated mental arithmetic task or a resting control period immediately prior to influenza vaccination. An enhancement of the antibody response to one of the influenza viral strains was found in women in the psychologically stressed group compared to controls.

Conclusion and Future Directions

There is now considerable evidence that chronic stress is associated with a poorer antibody response to a variety of vaccinations. These *in vivo* findings give greater credence to the often reported association between psychological factors and immune function. The next challenge is to examine whether interventions designed to reduce psychological stress or improve more positive psychological characteristics can result in enhanced vaccination responses. Further, it is important to determine whether the immunomodulation associated with either chronic or acute stress is sufficient to result in differences in actual infection rates following vaccination. These studies would more fully establish causality as well as having clear clinical implications for improving protection following vaccination, particularly in vulnerable populations.

Vasoactive Peptides

Vasoactive Peptides and the Pituitary Response to Stress

Integration of Central and Peripheral Responses to Stress

A Question of Physiological Relevance

Glossary

<i>Calcitonin gene-related peptide (CGRP)</i>	A peptide homologous in structure and function to AM.
<i>Chronotropism</i>	The rate of cardiac muscle contraction.
<i>Diuresis</i>	The excretion of water in urine.
<i>Inotropism</i>	The strength of cardiac muscle contraction.
<i>Intermedin</i>	The recently discovered member of the adrenomedullin-calcitonin gene-related peptide (AM-CGRP) family of peptides.
<i>Natriuresis</i>	The excretion of sodium in urine.
<i>Natriuretic peptides</i>	A family of three homologous mammalian peptides, encoded by three distinct genes, that are produced in heart and

Preproadrenomedullin-derived peptides

Receptor activity modifying proteins (RAMPs)
Salt appetite

the vasculature and that were initially discovered on the basis of their renal actions to stimulate sodium excretion.

One mammalian gene encodes a prohormone that is posttranslationally modified to yield two vasoactive peptides: adrenomedullin (AM) and proadrenomedullin N-terminal 20 peptide (PAMP).

Receptor proteins that provide selectivity for the actions of adrenomedullin and calcitonin gene-related peptide.

The behavior of selective ingestion of osmotically active solute.

Regardless of the operant definition, stress elicits significant, physiologically relevant changes in not only emotional behaviors, but also endocrine and cardiovascular function. Poised appropriately between the perception of a stressor and the integrative response to that insult are vasoactive peptides, factors that exert potent physiological effects in brain, pituitary gland, and the periphery. In many ways, these hormones serve to integrate the responses of multiple tissue systems in a manner parallel and complementary to the autonomic nervous system. Indeed, vasoactive peptides act in brain to modulate sympathetic efferent activity, fluid and electrolyte balance, and neuroendocrine responses to stress. In the pituitary gland, they significantly contribute to the regulation of

corticotroph function. In the periphery, these hormones determine vascular tone, cardiac pumping efficiency, adrenal hormone production and release, and, importantly, renal handling of fluid and electrolytes. Two families of vasoactive hormones, known to be released in response to numerous stressors, provide excellent examples of the integrative biology of the stress response. The natriuretic peptides and members of the adrenomedullin-calcitonin gene-related peptide (AM-CGRP) family of peptides are produced in brain and pituitary gland, as well as in the peripheral vasculature, heart, and kidney. They act both locally as autocrine factors and after release into the circulation as classic hormones to in some cases initiate and in others modify stress responses at the cellular and whole organ level.

Vasoactive Peptides

The simplest definition of a vasoactive peptide is a small protein that exerts either prorelaxant or procontractile effects in intact blood vessels. These effects may be endothelium dependent, requiring the recruitment of additional peptides, prostaglandins, or diffusible gases from the endothelial cell, or they may be endothelium independent, reflecting a direct effect on the vascular smooth muscle itself. Vascular tone is determined primarily by neurogenic mechanisms, largely mandated by the level of sympathetic activation. Circulating and locally produced factors also play important roles in the selective activation of distinct vascular beds and in the overall maintenance of vascular pressure, the single most important determinant of adequate perfusion of the vital organs in stress. Local factors not only directly affect vascular reactivity, but also, via presynaptic mechanisms, modify sympathetic tone. These factors also contribute to the maintenance of adequate perfusion pressures by altering cardiac performance and adjusting vascular volume.

Natriuretic Peptides

Originally discovered in extracts of cardiac atrium, the prototype of natriuretic peptides was originally named atrial natriuretic peptide (ANP) due to its isolation site, biological action, and protein structure. A second member of the family, originally thought to be produced in brain, but now known to be of almost exclusively myocyte (indeed, ventricular myocytes) origin, is B-type natriuretic peptide (BNP). Both ANP and BNP are released in response to volume overload, sensed by the myocardium as excess stretch. They share major actions to stimulate sodium and water excretion in the urine ([Figure 1](#)). ANP appears more relevant under physiological conditions, and

BNP seems to be recruited in more chronic conditions of volume/pressure overload. Production of at least ANP also occurs in brain and pituitary gland, and actions there related to stress are numerous and diverse. The third member of this family of peptides, all products of unique genes, is C-type natriuretic peptide (CNP). Produced predominantly in brain and vasculature, very little, if any, CNP is produced in the myocardium. Although CNP is a poor natriuretic and diuretic agent, it is a profound vasodilator and can exert apparently paradoxical effects on sympathetic tone via central nervous system (CNS) actions. Much is known of the molecular biology, pharmacology, physiology, and pathophysiology of the natriuretic peptides.

Proadrenomedullin-Derived Peptides and Their Homologs

Surprisingly, vasodilatory activities were isolated from extracts of a pheochromocytoma, and these peptides were later discovered to be posttranslational products of the same messenger RNA. Produced not only in adrenal medulla, but even more widely in the blood vessels, brain, and pituitary gland, these two vasodilatory factors exert complementary actions via unique signaling mechanisms ([Figure 2](#)). Adrenomedullin (AM), a 52-amino-acid peptide from the C-terminal portion of the proadrenomedullin precursor, exerts its vasorelaxant effects by stimulating nitric oxide synthase activity in endothelial cells of the vasculature. Proadrenomedullin N-terminal 20 peptide (PAMP), however, is a potent vasorelaxant due to its ability to exert presynaptic inhibition on sympathetic fibers innervating the vessel and to negatively modulate cholinergic activation of the chromaffin cells of the adrenal medulla and therefore reduce the level of epinephrine released in stress. Not all the actions of AM and PAMP are shared. For example, AM is a potent natriuretic and diuretic agent but does not affect catecholamine release significantly. A role for PAMP in sodium homeostasis also exists, however, as even in the absence of renotropic actions PAMP can stimulate sodium excretion due to its profound inhibitory effects on aldosterone secretion.

CGRP is a 37-amino-acid homolog of AM, and both are members of a larger family of peptides that includes calcitonin, amylin, and the recently described 47-amino-acid peptide intermedin (IMD; also named adrenomedullin-2). There is some evidence that these peptides may share an ancestral gene, and in addition to their structural similarities, they exert many shared biological activities (and perhaps receptors). CGRP, like AM, is a potent vasodilator when administered intravenously and has been demonstrated to inhibit aldosterone secretion *in vitro*.

Figure 1 Pharmacological actions of the atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP). AVP, vasopressin release; ACTH, adrenocorticotropin release; VR, venous return; BP, blood pressure; HCT, hematocrit; NPR-A, guanylyl cyclase A receptor; NPR-B, guanylyl cyclase B receptor; GFR, glomerular filtration; $U_{Na}V$, urinary sodium excretion; UV, urine volume. Also indicated is the production of C-type natriuretic peptide (CNP) in brain and urodilatin (URO), an N-terminally extended form of ANP in kidney. ANP and BNP are removed from the circulation by binding to the clearance receptor (NPR-C) and via degradation by neutral endopeptidase (NEP). Modified from the original and reprinted from Samson (1995), with permission of Humana Press.

When given into the CNS, like AM, it activates sympathetic tone, thus raising blood pressure. IMD exerts these same peripheral and central actions related to cardiovascular function and, like AM, exerts direct effects in the heart to increase contractility (inotropism) and beating frequency (chronotropism). Renal effects of IMD may parallel those of AM as well. It is not surprising that these homologous peptides exert similar actions (although unique effects may exist for each) since they share a common family of biological receptors. Those receptors are actually a complex of at least two proteins, the calcitonin receptor-like receptor (CRLR) and one of three possible receptor activity modifying proteins (RAMP1, RAMP2, or RAMP3). The relative combination of the respective RAMPs with the CRLR defines the specificity of the binding of each ligand. The CRLR–RAMP1 complex binds CGRP preferentially, while CRLRs in association with either RAMP2 or RAMP3

are the AM receptors. IMD binds promiscuously with all three CRLR–RAMP complexes, and thus it is not surprising that the hypotensive effects of IMD are at least partially blocked by relatively selective CGRP and/or AM antagonists.

Vasoactive Peptides and the Pituitary Response to Stress

Conventionally, the pituitary response to stress is considered to be the release of the hormone adrenocorticotropin (ACTH). The release of ACTH is controlled mainly by corticotropin-releasing hormone (CRH) levels in the hypophysial portal plasma; however, stimulation by vasopressin and oxytocin, as well as epinephrine, has been demonstrated. Thus, the effect of CRH can be modulated physiologically by factors also present in the portal circulation or by factors produced locally in the pituitary gland itself.

Natriuretic Peptides

ANP is produced in the hypothalamus, where it exerts inhibitory effects on the releases of vasopressin and CRH. These effects may have physiological relevance, as stress-induced ACTH secretion is accentuated in rats pretreated centrally with anti-ANP antiserum, and glucocorticoid negative feedback is reduced when endogenous, brain-derived ANP is neutralized with the same antibodies. The effects are not limited only to ANP, as central administration of CNP also inhibits the stress response.

In addition to production in neurons projecting to stress centers in the hypothalamus (the paraventricular nucleus in particular), ANP and CNP are produced in cells of the anterior pituitary gland, where again CNP appears to be the most abundant gene product. Indeed, both the natriuretic peptide A receptor (NPR-A), which binds ANP preferentially, and the natriuretic peptide B receptor (NPR-B), which

prefers CNP, are present. Even the third natriuretic peptide receptor (NPR-C), the clearance receptor, is found in the gland, although to a much lesser degree. Importantly, the NPR-A and NPR-B receptors have been localized to the corticotrophs, lactotrophs, and gonadotrophs. Both the NPR-A and the NPR-B are particulate guanylyl cyclase-linked receptors, activation of which results in elevated cellular levels of cGMP. ANP, but not CNP, potently stimulates the accumulation of cGMP levels in dispersed anterior pituitary cells. Activation of guanylyl cyclase is known in many cells to result in the stimulation of cGMP-dependent phosphodiesterases, which limit the activity of preformed cAMP. Because CRH stimulates ACTH secretion by activating adenylyl cyclase with the cAMP formed then stimulating protein kinase A activity, it was not surprising that ANP, but not CNP, could inhibit CRH-induced ACTH secretion in cultured pituitary cells.

What pool of ANP could act in this fashion *in vivo*? ANP not only is produced in the pituitary gland, but also is delivered in the portal blood. Thus, the peptide could be acting to circumscribe ACTH secretion via a local paracrine mechanism or via a more classical neuroendocrine fashion. Are these pharmacological effects of ANP in cell culture physiologically relevant? While one group failed to observe any significant effects of physiological doses of ANP on CRH-stimulated ACTH secretion in humans, two other human trials did reveal a significant inhibitory effect of intravenously administered ANP on ACTH release.

Preproadrenomedullin-Derived Peptides

The adrenomedullin gene is transcribed in the hypothalamus, and AM-immunoreactive positive neurons projecting to neuroendocrine centers related to stress have been identified. Indeed, direct application of AM caused depolarization of parvocellular neurons of the paraventricular nucleus (PVN) in brain slices. Although the chemical phenotype of those AM-responsive parvocellular PVN neurons was not identified, they are composed of at least two classes of neurons, both playing a role in the hypothalamic control of the stress response. One subset projects to median eminence and delivers releasing factors, including CRH, to the hypophyseal portal vessels for transport to the anterior pituitary gland. The other subset, also including some CRH-producing neurons, projects to autonomic centers in brain stem and thus may coordinate the cardiovascular stress response with that of the hypothalamic-pituitary-adrenocortical (HPA) axis. In fact, AM administration has been reported to increase Fos expression in CRH-positive hypothalamic neurons and to activate the HPA axis. Convincing evidence for a direct action of AM on CRH-producing neurons that project to median eminence comes from studies in which the ability of centrally administered AM to stimulate ACTH release was abrogated by pretreatment with a neutralizing anti-CRH antibody. The central action of CGRP to stimulate the HPA axis similarly was blocked by pretreatment with an anti-CRH antibody, and recently IMD was demonstrated to activate the HPA axis by stimulating CRH release into the median eminence.

While AM immunoreactivity is not abundant in the external layer of the median eminence, and thus a neuroendocrine role for AM or PAMP in the regulation of ACTH secretion cannot be predicted, AM gene products are widely distributed in the anterior lobe of the pituitary gland and binding for AM has been demonstrated. On the basis of the ability of AM and PAMP to inhibit angiotensin II and potassium-stimulated aldosterone secretion from zona

glomerulosa cells *in vitro*, it was predicted that the peptides might also inhibit ACTH release from corticotrophs in culture. Basal and CRH-stimulated ACTH secretion *in vitro* is inhibited significantly by doses of AM, which approximate those present in the gland *in vivo*. The effects are dose and time dependent and are not related to the well-known ability of the peptide to activate adenylyl cyclase in peripheral tissues. In fact, the mechanism of the inhibitory effect of AM on ACTH remains unknown, as the peptide did not stimulate adenylyl or guanylyl cyclase activity in these cell cultures and similarly did not alter the levels of nitric oxide present during the incubations. A direct effect on the membrane polarization state could be hypothesized; however, a potassium channel blocker, glybenclamide, did not alter the action of AM to inhibit ACTH secretion under basal conditions.

The second posttranslational product of preproadrenomedullin (PAMP) also inhibits basal ACTH in a time- and dose-dependent fashion. It too exerts this effect at physiological concentrations and, like AM, does not directly alter adenylyl or guanylyl cyclase activity *in vitro*. Unlike AM, PAMP does not affect CRH-stimulated ACTH secretion. The ability of PAMP to reduce basal, but not stimulated, hormone secretion suggested an effect on the membrane polarization state. Because PAMP has been reported to act in other cell lines via an ATP-sensitive potassium channel, the pituitary effect was hypothesized to be due to opening of such a channel and hyperpolarization of the corticotroph membrane. Indeed, the ATP-sensitive potassium channel blocker glybenclamide completely blocked the inhibitory action of PAMP on ACTH secretion.

It remains to be determined whether these *in vitro* findings reflect physiological relevance in the *in vivo* setting. However, evidence for an *in vivo* effect of at least AM on ACTH secretion comes from studies in conscious sheep where the intravenous, but not intracerebroventricular, administration of AM lowered plasma levels of ACTH. It will be important to determine how the endogenous production of AM and PAMP in the pituitary gland is regulated. In the periphery, inflammatory stimuli such as interleukins and tumor necrosis factor- α are potent stimulators of AM gene transcription and peptide release. Thus, proinflammatory signals may also regulate pituitary production of the peptides as well, and proinflammatory cytokines are known effectors of ACTH secretion.

It is in the pituitary gland that the biological actions of the members of the AM-CGRP-IMD family of peptides diverge. Unlike the inhibitory effects of AM on ACTH release, CGRP has been reported to

stimulate hormone secretion via a cAMP-protein kinase A-dependent pathway. On the other hand, IMD has been reported to lack significant effects on basal or CRH-stimulated ACTH release. Furthermore, IMD inhibits releasing factor-stimulated growth hormone (GH) secretion *in vitro*, which is quite the opposite of the reported actions of AM and CGRP to stimulate GH secretion. The effect of IMD on somatotroph function suggests the existence of an IMD receptor unique from the CRLR-RAMP receptor complexes. This *in vitro* action of IMD may be physiologically relevant since in rodents stress results in inhibition of GH release and this peptide acts both centrally and at the level of the pituitary gland to decrease GH release. The actual source of the IMD that may be exerting these actions is unknown; however, the gastrointestinal tract is a prime candidate, since the highest levels of the peptide have been detected in stomach, as well as in kidney and brain.

All three members of the AM-CGRP-IMD family of peptides exert behavioral effects that may reflect a response to stress. The peptides inhibit food appetite and water drinking when administered into the brain, and at least in the case of AM, the effects on water drinking and salt appetite have been shown to be physiologically relevant. It appears that the actions of AM are more related to fluid and electrolyte homeostasis and those of CGRP to energy intake. Intermedin exerts anorexigenic effects similar to those of CGRP; however, the actions of IMD on thirst more closely parallel those of AM.

Integration of Central and Peripheral Responses to Stress

The integrative response to stress requires a coordination of multiple organ systems. Because of their diverse sites and mechanisms of action, vasoactive peptides are excellent candidates for physiological regulators of these integrative responses. Natriuretic peptides provide the best example of factors that exert complementary actions in multiple tissue sites. Their ability to unload excess vascular volume via direct natriuretic and diuretic actions in kidney is matched by inhibitory actions on releases of the volume conservatory hormones vasopressin, renin, and aldosterone. Behavioral actions within brain also complement these renal effects. ANP not only stimulates fluid and electrolyte excretion, but also, in what is now known to be a physiologically relevant manner, inhibits water drinking and salt intake, thus allowing time for the renal mechanisms to compensate before the addition of new fluid volume to the already taxed vascular tree. In states of volume depletion, these mechanisms are inhibited, thus

permitting sodium and water retention and additional intakes to replenish lost volume. The blood pressure-lowering effects of the natriuretic peptides are not remarkable, but they can be demonstrated at pharmacological doses *in vivo*, and data from ANP and NPR-A knockout mice suggest an important role for the peptide in blood pressure regulation.

In times of excess secretion, such as during cardiac overload states, endogenous natriuretic peptides may unload the heart by a vasodilatory mechanism that is complemented by increases in vascular permeability. One group has demonstrated a sympatholytic effect of ANP in the brain stem, which would also lower vascular pressure. Thus, the actions of natriuretic peptides seem well coordinated to facilitate fluid and electrolyte balance and the response to volume stress. Whether the peptides play any role in psychogenic stress remains to be seen. However, the ability of both ANP and CNP to inhibit the hypothalamic drive for gonadotropin secretion suggests that some stress-induced infertility may involve the hypothalamic actions of these peptides. Evidence for the physiological relevance of this effect has been provided in studies employing selective cell targeting of NPR-B receptive neurons in hypothalamus.

Adrenomedullin gene products provide a very different example of the potential importance of vasoactive peptides in the body's response to stress. Because of its profound effects on brain, pituitary, vascular, adrenal, and renal mechanisms related to fluid and electrolyte homeostasis, overexposure of the body to high levels of AM could have disastrous consequences. AM potently inhibits water drinking and sodium appetite, ACTH secretion, aldosterone release, vascular tone, and renal fluid reabsorption. Thus, when released in large amounts, as in sepsis, potentially fatal hypotension and the resultant underperfusion of vital organ systems could result. Fortunately, the actions of AM, and to some degree PAMP, include compensatory effects that protect against cardiac collapse. Indeed, in clinical studies the levels of AM attained in plasma during sepsis predict survival, probably due to the cardioprotective effects of those high levels of peptide. Furthermore, transgenic overexpression of the AM gene in mice results in enhanced survival outcomes during experimentally induced septic shock.

How is this accomplished? In brain, AM and PAMP are sympathostimulatory. This may seem a paradox in light of the profound hypotensive effects of the peptide in the periphery. However, their action in brain may compensate for not only the vasorelaxant effects of the peptides, but also the ability of AM to dampen baroreflexes and thus the perception of volume depletion. This central activation of

sympathetic efferents may assure adequate perfusion of vital tissues. Similarly, direct effects of AM on cardiac contractility have been documented. While decreasing venous return by peripheral vasodilation, AM also exerts positive inotropic and chronotropic effects in heart, which can maintain ejection fraction and stroke volume, again protecting against cardiac collapse. At least one additional protective effect of AM has been demonstrated. Even in the face of profound hypotension, renal perfusion pressure is maintained due to the dilatory effects of the peptide on both afferent and efferent renal arterioles. Thus, AM and PAMP exert protective effects that assure perfusion of the vital organ systems during hypotension, and these mechanisms must be considered important for the response of an individual to stress.

A Question of Physiological Relevance

With the exceptions of CNS actions of both ANP and AM to inhibit thirst and salt appetite, of AM to stimulate vasopressin release, of CNP to inhibit GnRH release, and of ANP to contribute to blood pressure regulation during sodium excess, much of the current knowledge of the physiological relevance of the vasoactive peptides remains based solely on pharmacological evidences. Only recently have combinations of methodologies been attempted to identify and confirm physiological relevance. For example, the salt appetite-suppressive effect of AM was suggested to have physiological relevance by studies employing selective antibodies that neutralized endogenous brain-derived AM. These initial findings were then confirmed by the antisense oligonucleotide approach in studies in which excessive salt appetite occurred when the endogenous production of AM was interrupted.

Why is it important to establish the physiological relevance of any peptide's pharmacological effects? The obvious answer is the potential use of an exogenous peptide in a therapeutic setting. Less obvious is the importance of elucidating the potential involvement of a given peptide in the genesis of a pathological state. Because of their pleuripotent biological activities, vasoactive peptides hold promise for both therapeutic use and the diagnosis of evolving pathology. In particular, plasma BNP levels are now

accepted as diagnostic of the progression of cardiac overload in congestive heart failure in humans, and ANP is a clinical tool employed to unload excessive vascular volume in this disease. The ACTH-inhibiting effect of ANP during such treatment would certainly provide an extra therapeutic advantage. This again points to the significance of multiple sites and mechanisms of actions of vasoactive peptides during challenges to normal homeostasis, which by any definition mean stress.

The Posterior Pituitary Hormones

Vasopressin Synthesis

Vasopressin Release

Receptors

Vasopressin in the Brain

Vasopressin and the Hypothalamic-Pituitary Axis

Glossary

<i>Diabetes insipidus</i>	A condition caused by insufficient vasopressin in the circulation or inability of vasopressin to activate receptors in the kidney; manifest by polyuria and polydipsia.
<i>Hormone</i>	A peptide that circulates in the blood and exerts its biological effects by binding to specific receptors on select target tissues.
<i>Hypothalamus</i>	The part of the central nervous system residing above the pituitary, containing neurons that control vital functions (e.g., pituitary secretions, thermoregulation, and homeostasis in the autonomic, cardiovascular, and hydromineral systems).
<i>Median eminence</i>	The area at the base of the third cerebral ventricle that contains two zones: an inner zone that has axons in passage to the posterior pituitary and an external zone that contains the axon terminals of parvocellular neurons that synthesize and release peptides into adjacent portal capillaries.
<i>Neurohypophysis</i>	The posterior part of the pituitary, composed mainly of axon terminals of hypothalamic magnocellular neurosecretory neurons.
<i>Nonapeptides</i>	Peptides made up of nine amino acids.

Vasopressin is a nonapeptide that functions as a hormone in the blood and as a neurotransmitter or neuromodulator in the brain. Vasopressin is synthesized as a precursor molecule, prepropressophysin, within neurons with specialized functions. In magnocellular

neurosecretory neurons of the hypothalamus, the precursor is stored in vesicles and undergoes posttranslational processing during axonal transport to terminals in the neurohypophysis. Vasopressin release into the systemic circulation occurs in response to the activation of these neurons by specific stressors that challenge hydromineral balance (e.g., dehydration) and cardiovascular homeostasis (e.g., blood loss and hypotension). Once in the circulation, vasopressin assumes key hormonal roles by binding to V₁ type receptors on vascular smooth muscle to produce vasoconstriction and to V₂ type receptors in the kidney to increase water reabsorption and antidiuresis. Other peripheral actions include platelet aggregation; liver glycogenolysis; and secretion of aldosterone, insulin, and atrial natriuretic factor by the adrenal gland, pancreas, and heart, respectively. Vasopressin synthesized centrally in other hypothalamic and extra-hypothalamic neurons in the brain acts mainly through V₁ type receptors to mediate several functions, including the modulation of neuronal excitability via autocrine, paracrine, or transmitter mechanisms, to augment the release of adrenocorticotrophic hormone (ACTH) in the anterior pituitary during stress, to attenuate febrile responses, and to influence cognition and complex social behaviors.

The Posterior Pituitary Hormones

The discovery in 1895 that injections of extracts of beef pituitary increased arterial blood pressure marked the beginning of a century of research into the biology of the neurohypophysial hormones, identified as two structurally similar nonapeptides, oxytocin and vasopressin. Their main biological effects, the contraction of vascular and uterine smooth muscle and antidiuresis, were initially assessed by sensitive bioassays. Elucidation in the 1950s of the chemical structure of vasopressin as distinct from oxytocin permitted the development of specific radioimmunoassays, receptor agonists and antagonists, and techniques to investigate the molecular biology and function of vasopressin and oxytocin genes. Although discovered through their peripheral hormonal actions following their release from the posterior pituitary, an important aspect of this evolution was the recognition that vasopressin and oxytocin are also neuropeptides whose synthesis and release by different populations of neurons in the brain can influence a variety of central nervous system functions.

Vasopressin Synthesis

In Hypothalamic Magnocellular Neurons

Vasopressin and oxytocin molecules circulating as hormones in the blood originate from specialized magnocellular neurons, termed neurosecretory cells, located within the hypothalamic supraoptic and paraventricular nuclei and accessory magnocellular nuclei. The accessibility of the magnocellular neurohypophysial neuronal system has provided investigators with a valuable model to study peptide biosynthesis. In accordance with their separate biological roles, the genes for vasopressin and oxytocin are usually localized in different magnocellular neurons. Vasopressin- and oxytocin-synthesizing neurons also contain genes that code for other neuropeptides, and these may be co-activated and co-expressed together with vasopressin (or oxytocin) under appropriate circumstances. Consistent with other neuropeptides, synthesis occurs in the cell somata, initially resulting in the formation of a large precursor molecule called preproressophysin that is composed of a signal peptide, the nonapeptide vasopressin (arginine-8 vasopressin, AVP, in most mammals; lysine-8 vasopressin in pig), a putative carrier molecule neurophysin, and a 39-amino-acid glycoprotein (co-peptin, CCP). After packaging into large (160-nm) neurosecretory vesicles, preproressophysin undergoes further posttranslational processing during transport in axons to storage sites in the posterior pituitary.

Magnocellular neurosecretory neurons constitutively express vasopressin in their somata and axons. They also demonstrate an increase in vasopressin hnRNA and mRNA within minutes of exposure to a physiological stimulus (examples include a rise in plasma osmotic pressure and the unloading of peripheral baroreceptors as a consequence of blood loss). Osmotic, hypotensive, and immune stimuli are also powerful activators of several immediate early genes, including cFos and cJun, in these neurons. Details of the linkage between these genes and the signal transduction mechanisms that regulate vasopressin gene transcription in health and disease (e.g., ectopic production by small-cell lung cancers) are topics under investigation.

A lack of vasopressin in animals and humans results in diabetes insipidus, a condition characterized by polyuria and polydipsia. Central diabetes insipidus may occur because of a lesion in the hypothalamic-neurohypophysial pathway or, more rarely, as an autosomal dominant inheritance in which mutations have been detected in the vasopressin signal peptide or neurophysin molecules. The only genetic animal model for hypothalamic diabetes insipidus is the

Brattleboro rat; discovered 30 years ago, this animal fails to produce sufficient vasopressin due to a single base pair deletion in its vasopressin gene. The recent development of a vasopressin-null mouse may provide new insights into various roles of vasopressin in the stress response, cardiovascular regulation, and behavior.

In Parvocellular Neurons

Immunocytochemical and radioimmunoassay techniques reveal that vasopressin is present in other areas of the brain and spinal cord and in certain peripheral autonomic ganglia. In the brain, distinct groups of vasopressin-synthesizing parvocellular neurons may be recognized by their vasopressin-like immunoreactivity or through their ability to express vasopressin mRNA and hnRNA. The latter forms of gene expression reveal that vasopressin synthesis may depend on specific stimuli. For example, in the hypothalamic paraventricular nucleus, corticotropin releasing hormone (CRH)-synthesizing neurons may co-express vasopressin only during stress.

Vasopressin Release

Into the Systemic Circulation

Levels of vasopressin in the circulation (expressed as picograms per milliliter) are normally low to undetectable. Vasopressin is released into the systemic circulation from storage sites in the neurohypophysis in response to specific challenges to cardiovascular or hydromineral homeostasis, causing plasma levels to rise to >20 pg/ml. In some clinical circumstances associated with head trauma, congestive heart failure, liver cirrhosis, and cancer (e.g., small-cell lung carcinomas), humans have been found to have an excess of vasopressin in the circulation relative to their plasma osmolality, resulting in free-water retention and hyponatremia, a syndrome of inappropriate antidiuresis.

Circulating levels of the hormone are normally regulated through release from the neurohypophysis, a structure comprising mainly pituicytes and axon terminals of the hypothalamic magnocellular neurons that contain stored neurosecretory vesicles. Action potentials generated at the cell somata of the magnocellular neurons (in response to specific stimuli) propagate into the nerve terminals, thereby activating voltage-gated calcium channels that promote a rise in intracellular calcium and triggering exocytosis. The efficiency of this stimulus-secretion coupling mechanism is dependent on both the rate and pattern of discharge of action potentials invading the nerve terminals; release is optimized not only by an increase

in action potential frequency up to and beyond 20 Hz but also by the emergence of bursting or phasic patterns of firing.

Stimuli for release

Plasma hyperosmolality The osmolality of the plasma is sensed in the brain by a central osmosensor complex composed of neurons in the lamina terminalis along the anterior wall of the third cerebral ventricle in addition to the hypothalamic magnocellular neurons themselves. Recent electrophysiological studies indicate that magnocellular neurons are intrinsically osmosensitive; they contain mechanosensitive stretch-inactivated cation channels that sense changes in cell volumes consequent to a deviation from resting plasma osmolality (~290 mosmol/kg in humans). A rise in the osmolality of the extracellular environment initiates cell shrinkage; an ensuing increase in a membrane cationic conductance results in membrane depolarization and a subsequent increase in action potential generation once the membrane potential reaches threshold (around -50 mV). In the rat, the increase in activity of vasopressin-synthesizing magnocellular neurons usually initiates a unique phasic-bursting pattern of firing, an efficient trigger for stimulus-secretion coupling.

Hypovolemia and hypotension In mammals, information about the state of the peripheral cardiovascular system is continuously supplied to the brain via afferent pathways in the glossopharyngeal and vagus cranial nerves. Baroreceptors monitor the tone in the main arteries around the heart and lungs. A drop in arterial blood pressure, as might result from hemorrhage, decreases the input from baroreceptors. This information is channeled through catecholaminergic pathways that ascend through the brain stem to the hypothalamic magnocellular neurons, triggering an increase in their activity and initiating hormone release in the posterior pituitary.

In the Pituitary Portal Circulation

The external zone of the median eminence contains an abundance of axon terminals. Those that demonstrate vasopressin-like immunoreactivity arise mainly from parvocellular neurons in the hypothalamic paraventricular nucleus. A subpopulation of these are neurons that normally synthesize only CRH but that also contain inactive vasopressin genes that become expressed under conditions of prolonged stress and then co-release both peptides into the pituitary portal circulation from vesicles stored in these median eminence axon terminals. Receptors for vasopressin reside on anterior pituitary corticotrophs.

In the Brain

The neurohypophysial peptides are found in relatively high concentrations (in the picogram per microliter range) within the extracellular space in specific areas of brain. Because blood-born peptides are not seen in these concentrations and do not cross the blood-brain barrier in significant amounts, this reflects central release. Two likely sources are synaptic release from the axon terminals of central vasopressin-synthesizing neurons and exocytosis from somata and dendrites. The latter event is now well recognized as a mode of peptide release in the hypothalamic magnocellular neurons of the paraventricular and supraoptic nuclei. Here, high concentrations of vasopressin and/or oxytocin can be measured by microdialysis, cell somata and dendrites display neurosecretory vesicles with exocytotic profiles, and electrical events consistent with dendritic release can be recorded.

Stimuli for brain release Stressors such as social defeat and forced swimming are potent stimuli to trigger the release of vasopressin into the brain. Release sites may vary with the stimulus. For instance, social defeat is associated with vasopressin release in the paraventricular nucleus but not in the supraoptic nucleus and causes no change in levels of vasopressin in the plasma. Forced swimming, on the other hand, promotes vasopressin release in both the paraventricular and supraoptic nuclei, again with virtually no change in plasma vasopressin levels. This illustrates a dissociation between the mechanisms that trigger central versus peripheral release. Central release mechanisms have not been studied as extensively as those in the posterior pituitary.

In the Cerebrospinal Fluid

Vasopressin is present in the cerebrospinal fluid of many mammals. Unlike levels in the plasma, cerebrospinal vasopressin may exhibit large daily rhythms with high concentrations during daylight hours, suggesting that the origin is regulated by the suprachiasmatic nucleus, a regulator of circadian rhythms in the mammalian brain.

Receptors

Peripheral and central effects of AVP are mediated by at least three subtypes of G-protein-linked membrane-bound receptors. These fall into two classes, V_1 (V_{1a} vascular and V_{1b}/V_3 pituitary) and V_2 , based on second-messenger cascades and pharmacological properties. The activation of V_1 class of receptor

subtypes ($V_{1a}R$ and $V_{1b}R$) results in the hydrolysis of phosphatidyl inositol and an increase in cytosolic calcium. The activation of the V_2 receptor (V_2R) results in the stimulation of adenylate cyclase.

The V_1 Receptors

This receptor has been cloned, and its mRNA (visualized by *in situ* hybridization histochemistry) is seen throughout the brain, liver, and kidney; the $V_{1a}R$ mediates the vasoconstrictor and hepatic glycogenolytic actions of vasopressin and is thought to be the predominant vasopressin receptor in brain. A subtype of the V_1 class, the $V_{1b}R/V_3R$, has been characterized in the anterior pituitary where it regulates vasopressin-mediated ACTH release by potentiating the actions of CRH. $V_{1b}R$ mRNA has also been detected in the thymus, heart, lung, spleen, kidney, uterus, breast, and brain.

V_2 Receptors

The V_2 receptors and V_2R mRNA are abundant in the kidney renal tubules, where they mediate the well-established antidiuretic properties by promoting free-water reabsorption. Aquaporin 2, the water channel in apical collecting duct cells, is present in the membrane of cytoplasmic vesicles and is translocated to the apical membrane in response to vasopressin. Vasopressin regulates two types of aquaporin 2 expression: one prompt and the other sustained. The failure of vasopressin action in the kidney renal tubules results in nephrogenic diabetes insipidus, a disorder that may be inherited, resulting from mutations in the genes for vasopressin V_2 receptors and/or aquaporin 2.

Vasopressin in the Brain

Initial studies on avoidance behavior in the early 1960s provided the first clue that vasopressin and related peptides were involved in learning and memory processes. It is now recognized that centrally released vasopressin is involved in a variety of roles, including rewarded behavior and drug tolerance; social, reproductive, and feeding behaviors; temperature and cardiovascular regulation; stress; and circadian rhythms.

Vasopressin Pathways

Techniques that can specifically define vasopressin-relevant regions of brain (ligand-binding assays, immunocytochemistry, and *in situ* hybridization) in combination with lesions and tract-tracing methods serve to define a chemical neuroanatomy of vasopressin in the brain. Prominent among these are the

magnocellular neurons of the hypothalamic supra-optic, paraventricular, and accessory magnocellular nuclei and cells groups whose axons project to the posterior pituitary. The paraventricular nuclei also contain subsets of parvocellular neurons that synthesize vasopressin. Some of these neurons project to the median eminence and form a component of the hypothalamic-pituitary-adrenal axis; the expression of their vasopressin genes may be evident only under certain circumstances.

Other paraventricular and hypothalamic neurons that contain vasopressin constitutively project axons to the parabrachial nucleus, dorsal vagal complex, ambiguus nucleus, medial and ventrolateral medulla, and spinal cord areas; these are likely to participate in control of regulatory functions attributed to the autonomic, sympathetic, and parasympathetic nervous systems (e.g., heart rate, blood pressure regulation, and release of adrenal medullary hormones).

Vasopressin-immunoreactive neurons occupy the dorsomedial core of the hypothalamic suprachiasmatic nucleus (SCN), site of a biological clock in the mammalian brain. These cells project into the medial hypothalamus and contribute to the entrainment of circadian rhythmicity in hypothalamic neuroendocrine and thermoregulatory functions. Functions of a prominent extrahypothalamic projection to the midline thalamic paraventricular nucleus remain to be defined. SCN vasopressin-synthesizing neurons are the likely source for the circadian rhythmicity in vasopressin observed in the cerebrospinal fluid.

Vasopressin neurons in the bed nucleus of the stria terminalis and medial amygdaloid nucleus project to the lateral septum, ventral septal nucleus, olfactory tubercle, lateral habenular nucleus, midbrain central gray, dorsal raphe nucleus, locus coeruleus, and ventral hippocampus.

Factors Affecting Central Vasopressin Gene Expression

Differing levels of mRNA indicate that vasopressin expression is not uniform. For example, adrenal steroids block vasopressin mRNA expression in the parvocellular neurons in the paraventricular nucleus but not in other brain areas. Vasopressin expression in lateral septum and medial amygdala requires the presence of gonadal steroids; most vasopressin mRNA disappears within a week of castration. How gonadal steroids work remains unclear because there are no recognizable androgen- and estrogen-responsive elements on the promotor region of the vasopressin gene. Presumably, these steroids do not affect mRNA transcription but, rather, regulate vasopressin mRNA levels at a posttranscriptional level because castration decreases the length of the mRNA poly(A) tail in the

bed nucleus of the stria terminalis, whereas testosterone increases it, thereby influencing the stability of the vasopressin mRNA.

Electrophysiology of Central Vasopressin Receptors

The exogenous application of vasopressin alters the excitability of neurons in a variety of areas, including the hippocampus, hypothalamus, brain stem, and spinal cord, all regions containing vasopressin fibers and/or neurons. In most instances, the response to vasopressin is manifested as an increase in neuronal firing, blockable with V_1 receptor antagonists. Mechanisms vary with the areas tested. Most investigations have focused on direct, tetrodotoxin-resistant actions mediated via postsynaptic receptors. For example, in rat facial nucleus, vasopressin receptors produce depolarization mediated by nonselective cationic channels. In the lateral horn of the neonatal rat spinal cord, vasopressin acting at G-protein-coupled V_1 type receptors produces depolarization in spinal preganglionic and other lateral and ventral horn neurons by decreasing a resting potassium ionic conductance and/or increasing a nonselective cationic conductance. Other actions are indirect, involving presynaptic receptors that attenuate glutamatergic or GABAergic neurotransmission. As previously reported, vasopressin is released locally by magnocellular neurons and the peptide is proposed to act in an autocrine or paracrine function to alter the excitability of the neurons responsible for its synthesis, either directly or through synaptic modulation. Calcium-imaging studies in dissociated vasopressin-synthesizing neurons from rat supraoptic nucleus reveal that signaling at vasopressin receptors involves calcium influx through L, N, and T type channels, an auto-regulation that seems to involve the activation of both protein kinase C- and adenylate cyclase-linked intracellular pathways.

Vasopressin and Thermoregulation

Studies in a variety of mammals have demonstrated the fever-reducing effects of vasopressin and the fever-enhancing actions of V_{1a} receptor antagonists injected into the ventral septal area. It is likely that this area receives its innervation from the bed nucleus of the stria terminalis. Interestingly, this is where electrical stimulation can attenuate pyrogen-induced fever, an effect that is blockable by injection of a V_{1a} receptor antagonist into the ventral septal area. Castration, which is followed by the disappearance of vasopressin in the septal area, lengthens pyrogen-induced fever, presumably because of a reduction in the amount of releasable vasopressin.

Vasopressin and Cognition

Extensive animal research has established a role for vasopressin in learning and memory. Less clear are the outcomes of similar efforts in humans. The hippocampal system has a prominent role in learning and memory, and current observations indicate a facilitating effect of vasopressin and vasopressin analogs on retrieval and relearning processes, mediated by both vasopressin V_1 type and oxytocin receptors located mainly in the ventral hippocampus.

Vasopressin, Monogamy, and Social Behavior

The neurohypophysial peptides have been implicated in the central mediation of complex social behaviors such as affiliation, parental care, and territorial aggression. For example, in the prairie vole, research suggests that vasopressin is involved in the control of several behaviors associated with monogamy, including pair bonding, paternal care, and mate guarding. Molecular studies suggest that changes in the regulation of oxytocin- and vasopressin-receptor gene expression underlie species differences in receptor distribution and might provide a mechanism for the evolution of monogamy in certain rodent species.

Vasopressin and the Hypothalamic-Pituitary Axis

The hypothalamic paraventricular nucleus contains two categories of neurosecretory neurons capable of synthesizing vasopressin. We have already referenced the magnocellular neurons that project their axons through the internal zone of the median eminence to the neurohypophysis. The following refers to a subpopulation of parvocellular paraventricular neurons capable of co-synthesizing CRH and vasopressin.

Vasopressin in Corticotropin Releasing Hormone Neurons

Under resting conditions, most paraventricular nucleus neurons that synthesize CRH neurons do not normally contain detectable levels of vasopressin. The expression of their vasopressin genes can be rapidly switched on by a variety of acute, repeated, or chronic challenges. Information revealing the presence of such challenges or stressors may reach the parvocellular neurons via several neuronal pathways: (1) descending inputs from circumventricular organs in the lamina terminalis along the anterior wall of the third cerebral ventricle, signaling information about osmolality, cytokine, and hormonal molecules in the circulation; (2) projections from diverse limbic system areas, conveying inputs related to psychological or emotional stress; (3) ascending inputs from catecholaminergic

neurons in the dorsomedial and ventrolateral medulla, relaying information related to autonomic and cardiovascular regulation; and (4) unspecified local intrahypothalamic innervations, including recurrent feedback pathways among these neurons themselves. Presumably the content and meaning of the information conveyed via different pathways reflects stimulus specificity and will engage different populations of paraventricular neurons to respond, thereby accounting for the different patterns of vasopressin mRNA and hnRNA expressed among populations of hypothalamic neurons in response to different stress paradigms.

The signaling that regulates the expression of the vasopressin gene in these cells remains to be defined. Distinct from their magnocellular counterpart, these parvocellular neurons contain type 2 glucocorticoid receptors that mediate a direct inhibitory effect of corticosteroids on neuropeptide gene expression. The removal of the adrenals, the source of this circulating corticosterone, triggers vasopressin synthesis and upregulates CRH synthesis in populations of parvocellular paraventricular nucleus neurons; the peptides are co-packaged into dense core vesicles, transported to the zona externa of the median eminence, released into the hypophyseal portal circulation, and carried (as hormones) into the anterior pituitary.

Vasopressin in the Anterior Pituitary

In the anterior pituitary, vasopressin potentiates the CRH-induced release of ACTH by binding to specific V_{1b} receptors on the corticotrophs, activating the inositol phospholipid cycle and protein kinase C, mobilizing calcium from intracellular stores, and triggering the release of ACTH from the rapid turnover pool. Genetically vasopressin-deficient Brattleboro rats have a blunted corticosterone response to certain forms of stressful stimuli, presumably reflecting the contribution normally made by vasopressin to the ACTH released by a stressor.

Glossary

Autoimmune disease A disease produced when the body's normal tolerance of its own antigenic markers on the surface of cells is lost.

Cohort study An observational study design commonly used in epidemiological studies of populations exposed to pathogens that could result in future diseases.

Diagnostic Interview Schedule (DIS) A mental health diagnostic interview based on standard psychiatric nomenclature that made population mental health surveys and population-level estimates possible.

Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III) The third edition of standard psychiatric nomenclature used to classify all emotional and mental health disorders in 1980 and the edition in which the definition of PTSD was included.

Heritability The proportion of variance of the liability to a disease that is due to shared genetic factors.

Hypothalamic-pituitary-adrenal (HPA) system Three key anatomic structures that collectively participate in hormonal responses to stressors by regulating human neuroendocrine functions and, hence, the body's adaptation to environmental stressors.

National Vietnam Veterans Readjustment Study (NVVRS) A national cross-sectional survey of male and female Vietnam veterans and non-veterans conducted to determine the prevalence and etiology of psychosocial readjustment problems and mental disorders among Vietnam veterans.

Operation Ranch Hand The U.S. military's operational code name for the application of herbicides (chiefly agents orange, blue, green, pink, purple,

and white) in Vietnam by aircraft in order to destroy enemy cover and food crops.

A follow-up study of the health status of the men involved in the Operation Ranch Hand herbicide operations.

A specific disabling psychiatric disorder that develops after exposure to psychologically traumatic events; the disorder could last for decades. Symptoms include the reexperiencing of the event, avoidance of stimuli related to the event, and persistent symptoms of increased arousal associated with the event.

A field of medical research that focuses on the association between neuroendocrine function and psychological status, especially as this relates to steroidogenic biological alterations and psychiatric illness.

A group of symptoms of a disordered function related to one another by means of a common pathology.

A national cohort study of male, U.S. Army Vietnam-theater and non-Vietnam-theater veterans, conducted to determine the prevalence and etiology of diseases and medical conditions associated with Vietnam service.

A registry composed of male twin pairs who both served in the U.S. military between 1965–1975 in order to study the effect of genetic factors on health status.

The Vietnam War

Although U.S. involvement in the Vietnam War officially ended over 30 years ago for the 3.14 million men and 7200 women who served there, the impact of their postwar experiences altered society in many ways. The postwar experiences of Vietnam veterans were different from veterans of many previous wars. For example, unlike earlier U.S. wars in the twentieth century, the Vietnam veteran returned home from a conflict that was controversial and unpopular. Furthermore, many veterans were draftees who often came from lower socioeconomic (SES) households. In addition, of all men eligible for the military draft, only a specific subgroup was primarily inducted, due to the Selective Service System's deferment policy, which generally exempted men from higher SES groups. Within this context, it became clear to at least some health-care professionals during the war

that many returning veterans were experiencing postwar adjustment problems. During this period, the work of Charles Figley stood out as a classic in stress research because it documented the emotional and psychological trauma many veterans began to manifest by war's end. Based on Figley's work, and that of others, health-care researchers and medical professionals in the late 1970s formulated specific etiological models of the pathogenesis of mental disorders among Vietnam veterans. They also contributed to the development of case definitions to characterize these syndromes. These efforts eventually culminated in the inclusion of posttraumatic stress disorder (PTSD) in the *Diagnostic and Statistical Manual of Mental Disorders* (3rd edn.; DSM-III). Once this was achieved, more accurate assessments of the scope and nature of traumatic stress (and related disorders) among Vietnam veterans and others were possible. Finally, studies of the postwar experiences of Vietnam veterans have led to many research developments and have accelerated the accumulation of knowledge related to the psychology and biology of PTSD, including the possible long-term medical and health consequences of this syndrome.

Although clinical documentation of the adverse psychological effects of combat exposure goes back at least as far as the U.S. Civil War, the etiology of these syndromes were neither clearly understood nor well defined. Ninety years ago during World War I, soldiers with acute adverse psychological reactions after combat were believed afflicted with shell shock, thought to result from the concussion effects of artillery bombardments. During World War II, combat fatigue was used to categorize soldiers exhibiting acute adverse psychological reactions after combat because it was thought that exhaustion played a role in this condition. From the 1950s to 1970s, the term war neurosis often was used to broadly characterize soldiers' adverse psychological reactions after combat. For example, the psychiatric literature during this period associated a wide range of postwar psychological problems with combat exposure, including irritability, jumpiness, disturbed sleep, hysteria, disorientation, and panic attacks. However, for years the long-term effects of combat exposure remained elusive, in part because of a poor case definition and in part because reliable and valid observational studies were not available until years after World War II. After reviewing these and other findings related to natural disaster and concentration camp survivors, Dohrenwend concluded that there was clear and compelling evidence that many individuals develop functional psychiatric disorders after extreme stress exposures that had not been present before these experiences, a discovery that had been made earlier by Freud.

Vietnam Veteran Studies

Initial Research

Initial studies of the postwar experiences of Vietnam veterans provided the first clinical and scientific evidence linking combat exposures in Vietnam to post-discharge problems and adjustment difficulties also observed among previous veterans. However, in part because Vietnam veterans often came from lower SES groups, the postwar status of these veterans was controversial. In addition, many early studies were methodologically flawed. One difficulty was that these studies were limited because of biases associated with using nonrepresentative samples. Another problem was the use of nonstandardized mental health measures or the use of measures that assessed only mental health symptoms. Thus, although clinicians had observed that many individuals exposed to combat exhibited certain postwar syndromes afterward (including hyperalertness, exaggerated startle responses, sleep disturbances, and other symptoms) linking these to combat exposure was problematic because of existing methodological shortcomings. However, when DSM-III was being developed in the late 1970s, clinicians and others involved with Vietnam veterans were successful in eventually incorporating these syndromes into DSM-III under the diagnostic nomenclature defining PTSD, originally labeled the post-Vietnam syndrome and later conceptually broadened to include other types of trauma, such as sexual abuse. Once PTSD was included in DSM-III, undertaking large-scale, standardized surveys of Vietnam veterans was feasible and had other research benefits. During this early research period, Robert Laufer's Legacy Study, although not based on a true probability study, stood out as a landmark investigation. This is because it included over 1000 subjects (both Vietnam veterans and civilians) and used several standard symptom scales common in the 1960s and 1970s. Thus, at the time, this study provided the best assessment of the mental health status of Vietnam veterans and served as a benchmark for future studies.

Later Research

As part of Public Law 98-160, the U.S. Congress in 1983 mandated that research on Vietnam veterans be undertaken to determine "the prevalence and incidence of post-traumatic stress disorder and other psychological problems in readjusting to civilian life." In addition to Public Law 98-160, the U.S. Congress passed other public laws mandating studies of the health effects of Vietnam service. As a consequence of these new laws, several well-designed

cohort studies of Vietnam veterans were undertaken during the 1980s. These studies avoided many of the shortcomings of previous research, chiefly because of advancements in sampling and measurement that evolved from earlier research. One of these included the availability of the Diagnostic Interview Schedule (DIS), which for the first time permitted the gathering of DSM-III psychiatric diagnoses by means of population surveys, something previously not possible. This later research confirmed that Vietnam combat veterans had higher rates of postwar adjustment difficulties, mental health disorders, medical morbidity, and postwar mortality than non-combat veterans or comparable nonveterans. Most important, however, these studies indicated that the postwar adjustment difficulties and health problems experienced by these veterans were often due to combat exposures in Vietnam, not to the selection biases or measurement inadequacies that had affected earlier studies. Among the later studies, the National Vietnam Veterans Readjustment Study (NVVRS), which involved over 2000 Vietnam-theater and non-theater veterans (in addition to hundreds of civilian nonveterans), is considered one of the most comprehensive psychosocial assessment to date. The NVVRS indicated that 15% of male Vietnam veterans were current PTSD cases (9% of female veterans) and that 31% of male veterans (27% of female veterans) had PTSD during their lifetimes. Those with PTSD also were more likely to have other stress-related psychiatric disorder, such as depression and anxiety disorders, as well as many other postwar adjustment problems. The NVVRS further indicated that the PTSD-positive veterans often had profoundly disrupted lives in almost every domain of life, including in employment and family relationships. Furthermore, the prevalence of PTSD and other postwar psychological problems were found to be significantly higher among those with greater combat exposure and among Hispanic and African American veterans.

However, as significant as the psychosocial consequences of the war was for Vietnam veterans, their postwar experiences went beyond psychosocial outcomes. For example, the Vietnam Experience Study (VES) indicated that Vietnam veterans had higher rates of postwar mortality in the first 5 years after discharge, primarily due to suicides, homicides, drug overdoses, and motor vehicle accidents. Furthermore, VES findings related to the postwar medical morbidity experienced by these veterans confirmed that Vietnam-theater veterans as a group had higher rates of health-care use and reported themselves to be in poorer health than veterans without Vietnam service. In addition, theater veterans also tended to have

higher rates of hearing loss, evidence of past hepatitis B infection, and higher thyroid-stimulating hormone levels after discharge. In addition, when the postwar health status of Vietnam veterans was examined in relation to whether the veteran had PTSD, PTSD-positive veterans had substantially higher (i.e., 50–150% greater) postwar rates of many major chronic diseases, including circulatory, nervous system, digestive, musculoskeletal, and respiratory diseases, even after controlling for the major risk factors for these conditions. For example, 25% of PTSD-positive veterans reported physician-diagnosed circulatory diseases nearly 20 years after the service (vs. 13% of PTSD-negative veterans) and 19% reported physician-diagnosed nervous system disorders (vs. 6%). Altogether, 68% of PTSD-positive Vietnam veterans reported the occurrence of a chronic disease-related medical condition 20 years after Vietnam service (vs. 48% of PTSD-negative Vietnam veterans). Finally, PTSD-positive veterans also were significantly more likely to show electrocardiographic evidence of myocardial infarction and to have abnormally high white blood cell counts ($>11,000/\text{mm}^3$) and other immune system abnormalities 20 years after military service.

The most compelling evidence, however, linking PTSD to adverse health outcomes was a VES study that examined the causes of death among 15,288 male U.S. Army veterans 30 years after their military service (see [Table 1](#)). The analyses adjusted for race, Army volunteer status, Army entry age, Army discharge status, Army illicit-drug abuse, intelligence, age, and for cancer mortality, also pack-years of cigarette smoking. The findings indicated that adjusted postwar mortality for all, cardiovascular, cancer, and external causes of death (e.g., motor vehicle accidents, accidental poisonings, suicides, homicides, and injuries of undetermined intent) was associated with PTSD among Vietnam-theater veterans ($N = 7924$), with hazards ratios (HRs) of 2.2 ($p < 0.001$), 1.7 ($p = 0.034$), 1.9 ($p = 0.018$), and 2.3 ($p = 0.001$), respectively. For Vietnam-era veterans with no Vietnam service ($N = 7364$), PTSD was associated with all causes of mortality ($\text{HR} = 2.0$; $p = 0.001$). PTSD-positive Vietnam-era veterans also appeared to have an increase in external-cause mortality as well ($\text{HR} = 2.2$; $p = 0.073$). This study essentially suggested that Vietnam veterans with PTSD were at approximately twice the risk of postwar death from multiple causes. Other postwar studies were also conducted, such as the Operation Ranch Hand Study, which sought to assess the postwar health effects of exposure to herbicides used in Vietnam. Others include the Vietnam Era Twin (VET) studies, which focused on the genetic liabilities for PTSD, substance abuse, and other mental health disorders, not just the impact of Vietnam service.

Table 1 Cox proportional hazards regressions: crude and adjusted hazard ratios by veteran and PTSD status^a

^dN = 7364; person-risk years = 110,553; total PTSD cases = 214.

^eN = 7924; person-risk years = 119,453; total PTSD cases = 836.

To date, however, the VES has provided the most compelling evidence related to the adverse health effect of combat service and PTSD during that conflict.

Psychobiological and Biomedical Findings

There are clinical reasons to expect alterations in neuroendocrine system functions in chronic PTSD cases because long-term changes in the HPA system and the sympathetic arm of the autonomic nervous system have been reported following exposure to extreme stress. Evidence suggests that the physiological arousal often observed during the recollection of traumatic events is associated alterations in the neuroendocrine functions linked to the sympathetic-adrenomedullary and HPA stress axes. In the case of PTSD, it is thought that these neuroendocrine alterations reflect the consequences of an extreme state of physiopsychological conditioning that occurs following severe stress exposures. Furthermore, although this conditioning response is initiated in the central nervous system (CNS), it is subsequently carried out by multiple endocrine mechanisms that have wide-ranging effects on the body and nervous system. Similar findings related to this physiological-emotional conditioning process have also been observed with animal models.

Several studies have reported lower cortisol levels among Vietnam veterans with PTSD, as well as increased catecholamine concentrations. Furthermore, one recent large-scale study, based on the VES and involving thousands of veterans, found not only that Vietnam-theater veterans with current PTSD had lower cortisol but that past combat exposure levels were associated with plasma cortisol concentrations in an inverse dose-response relationship (see Figure 1). In brief, research with Vietnam combat veterans suggests that PTSD-positive veterans tend to have lower cortisol levels but, paradoxically, higher catecholamine concentrations, together with heightened responses of the stress system to traumatic memories and other stimuli associated with the original trauma. It is known that chronicity and excessiveness of stress system activation can lead to pathogenesis, causing weight changes, depression, hypogonadism, and other systemic alterations, including increased metabolic load on the body's systems. Thus, the physiological findings for PTSD-positive Vietnam veterans suggest that past traumatic stress exposure has resulted in neuroendocrine system alterations that make veterans potentially susceptible to a host of chronic diseases. As noted, PTSD-positive Vietnam veterans were found to have higher postwar rates

Figure 1 Adjusted plasma cortisol concentrations and standard errors bars (95% confidence limits) for Vietnam-theater veterans by combat exposure levels ($N = 2457$). Results shown are for morning, fasted plasma cortisol (in micrograms per deciliter). Combat level was measured by the Combat Exposure Index scale, a standard measure of combat exposure. Cortisol results are adjusted for demographic variables, alcohol use, drug use, smoking status, and body mass index using analysis of covariance. A trend test for cortisol by combat exposure level was statistically significant ($p = 0.0001$), confirming the inverse dose-response association between cortisol and combat exposure. Adapted from J. A. Boscarino (1996), Post-traumatic stress disorder, exposure to combat, and lower plasma cortisol among Vietnam veterans: findings and clinical implications, *Journal of Consulting and Clinical Psychology* **64**, 191–201. Reprinted with permission from the American Psychological Association.

of many chronic diseases, reinforcing this neuroendocrine-dysregulation disease hypothesis, which represents a cornerstone in human psychoneuroendocrinology research.

Related to HPA dysregulation, it has been suggested that PTSD-positive veterans may be at risk for autoimmune diseases as well. For example, although there have been inconsistencies, investigators, as previously noted, have found that individuals who developed PTSD, particularly men exposed to combat, appeared to have lower plasma cortisol concurrent with higher catecholamine levels. As suggested, Vietnam veterans with current PTSD not only had lower cortisol, but this had an inverse dose-response relationship with combat exposure. In addition, also as previously noted, research indicated that Vietnam veterans with current PTSD had clinically elevated leukocyte and T-cell counts, and similar findings have been reported in nonveteran studies as well. These veterans were also found to have other significant neuroendocrine abnormalities, such as elevated thyroid hormones. Consistent with these clinical findings, it has recently been reported that PTSD was in fact associated with several autoimmune diseases among Vietnam veterans, including rheumatoid arthritis and psoriasis. Again, analogous results have been reported in animal models as well. Of course, not all of the variance in disease outcomes should be associated directly with PTSD. Research with the VET Registry suggested that about one-third of the liability for PTSD was associated with genetic factors. Some of the same genes that make one liable for PTSD could also make one liable for specific diseases as well.

Studies of Other Veteran Populations after Vietnam

Following the first Persian Gulf War (PGW) in 1991, cohort studies were again used to evaluate the health impact of this conflict on war-theater military personnel. These studies are still in progress, and a number of them evolved from or were related to the original NVVRS and VES research designs. The PGW research to date has established a link between service in the PGW and mental illness, postservice injury, chronic fatigue syndrome, and other multisymptom conditions. The reasons for these associations are still being investigated, and the results from PGW research are being used to inform a new generation of veteran studies, related to personnel deployed in the Afghanistan and Iraq theaters of war following the September 11, 2001, attacks. For these recent conflicts, however, military personnel were being assessed both before deployment and after return, something

rarely done in the past but often desired after service exposure had occurred. Finally, following the September 11 attacks in New York City (NYC) in 2001, a number of the investigative teams, funded by the National Institutes of Health (NIH) and the Centers for Disease Control (CDC) to assess the population impact of this event, used the prospective cohort method as well as measurement instruments that had been developed originally for Vietnam veteran population studies. Thus, the field of disaster epidemiology has emerged as a subspecialty within epidemiology, informed, at least in part, by the original work with Vietnam veterans over the previous decades.

Implications for Medical Sciences, Research, and Treatment

The postwar findings reported for Vietnam veterans documented that veterans exposed to combat have more stress-related psychosocial disorders, altered neuroendocrine functions, higher medical morbidity, and greater mortality years after the war. The scientific findings related to the postwar experience of the Vietnam veteran suggest that psychobiological models are probably required to understand the impact of this experience on the lives of those who served there. For example, it has been suggested that traumatic stressors act as unconditioned aversive stimuli that evoke severe physiological distress. Consequently, previously neutral external stimuli (e.g., the sound of a helicopter) and internal stimuli (e.g., physiological states) that accompanied the traumatic stressor, can function as conditioned stimuli capable of producing psychological and physiological distress when the traumatic stressors are no longer present. Experience with psychotherapy treatments suggests that when stress victims are gradually exposed to aversively conditioned stimuli the symptoms may decrease because desensitization to the stressor could occur. A psychotherapeutic technique often used in PTSD therapy with veterans is to teach the patient to verbalize the traumatic experience with the help of a support group consisting of other veterans. This process allows veteran to redefine the external and internal stimuli that affect psychological arousal, develop better self-control, and, with assistance, desensitize him- or herself to a range of thoughts, actions, and situations associated with the traumatic events. A more structured and currently widely used approach that appears to be effective is cognitive-behavioral therapy. Thus, psychosocial processes appear to be instrumental in treating a condition that is psychosocial in origin but that also has a physiobiological basis – that is, research with Vietnam veterans and

others tells us that PTSD has both a psychosocial and a physiobiological foundation.

The recognition of a multifactorial PTSD model is consistent with the report that both pharmacotherapy and cognitive-behavioral psychotherapy are effective in treating PTSD. In the case of pharmacotherapy, the pathophysiology of PTSD, in part, appears to involve the serotonergic and the noradrenergic systems; thus, drugs known to potentiate these mechanisms have been effective. In the case of cognitive-behavioral therapy, this approach has been found to be effective in reducing PTSD-related symptomatology by achieving desensitization to stressful stimuli, by increasing control of adverse arousals, by enhancing anxiety management, and by using other known behavioral-psychological mechanisms. Although the underlying interventional mechanisms differ for pharmacological versus cognitive-behavioral therapy (e.g., pharmacokinetic vs. psychological), the outcomes are similar – the psychopathology and underlying pathophysiology are reduced and fewer adverse patient symptoms are manifested, hence lowering the risk of other adverse outcomes. Thus, we expect that as trauma-related symptoms are reduced through treatment, the risk for other adverse outcomes will also decrease. Recent research has, in fact, confirmed this hypothesis in NYC following the September 11 attacks. For example, it has been reported that NYC adults who received emergency crisis counseling at work shortly after the attacks not only had better mental health outcomes but also had better outcomes in terms of binge drinking, alcohol dependence, and alcohol consumption, lowering the possibility of future adverse health outcomes.

Although the findings discussed here chiefly involve veterans, exposure to combat, they are applicable to other populations. Traumatic stress reactions occur among individuals exposed to extreme, life-threatening situations, including natural disasters, physical attacks, wartime combat, and other situations. In addition, it is likely that human exposure and response to stress take place along a stress continuum, with traumatic stress on one end of this continuum. Furthermore, genetic liability is also likely involved with respect to whom may succumb to PTSD. Finally, the postwar experiences of the Vietnam veteran suggest that more than psychosocial explanations are needed to understand PTSD and to treat it effectively. In addition to higher-order cognitive models, findings in Vietnam veteran suggest lower-order biological models are also necessary. Research also consistently suggests that those with less social support exhibit greater levels of traumatic stress, which may explain the high rates of PTSD among Vietnam veterans, given the low community support during and after the war. This finding has clinical implications for the future treatment of both combat and noncombat-related stress victims.

Conclusion

Psychoneuroendocrinology represents a growing area of medical research that focuses on the association between neuroendocrine function and psychological status, especially as this relates to steroidogenic biological alterations and psychiatric illness. Just as with other areas of medicine – orthopedics, plastic surgery, emergency medicine, and so forth – developments in

Table 2 Key biological correlates of PTSD among a national random sample of Vietnam veterans^a

Biometric measure	PTSD negative (%)	PTSD positive (%)	P value
White blood cell count elevated	2.8	4.6	0.063
Total lymphocytes elevated	4.2	6.8	0.023
T lymphocytes elevated	2.9	6.2	0.001
B lymphocytes elevated	9.9	13.7	0.032
CD4 cells elevated	3.5	5.6	0.055
CD8 cells elevated	2.4	5.9	<0.001
Erythrocyte sedimentation rate elevated	6.1	9.6	0.013

Thyroxine (T ₄) elevated	1.7	5.0	<0.001
Immunoglobulin-A elevated	16.4	23.5	0.001
Immunoglobulin-M elevated	1.2	3.4	0.001
Dehydroepiandrosterone reduced	2.3	4.6	0.008
Cortisol/dehydroepiandrosterone ratio elevated	4.4	7.1	0.023
N =	4139	323	–

^aData are from the Vietnam Experience Study and represent a national random sample of male U.S. Army veterans of the Vietnam War era, half of which served in Vietnam and half of which served elsewhere. PTSD cases represent both combat and noncombat cases. Assessment was done approximately 20 years after military service. PTSD, posttraumatic stress disorder.

military medicine and veterans' health have been translated into medical advances for other populations. For example, today, research related to the biological and medical consequences of anxiety disorders is more commonplace, as are epidemiological studies of other veteran populations and nonveteran studies involving exposure to human-made and natural disasters.

The medical promise of this body of research can be illustrated using the findings shown in [Table 2](#). As shown, PTSD-positive veterans have a distinct clinical profile, suggesting an increased inflammatory response related to a broad range of potential pathophysiology that could be associated with a host of diseases, including cardiovascular and autoimmune diseases. The reasons for the findings shown in [Table 2](#) are not clear at this time; they may be related to biological, psychological, or behavioral factors (or a combination of these) associated with PTSD and research also suggests that genetic factors are indeed involved. What is clear is that this area of research holds promise for understanding the psychosomatic basis for the causes and prevention of many human diseases. In conclusion, despite of the suffering caused by Vietnam War, or perhaps because of it, the postwar experiences of the Vietnam veteran have resulted in significant advances in our knowledge about the nature and consequences of human stress exposures and will probably result in future medical advances that cannot currently be imagined.

Types of Biological Influences

Summary

Glossary

Adoption studies

Research wherein a child with one set of biological parents and a different set of psychological parents is studied.

Biological environmental influences

Events that affect a person biologically but are not encoded into the person's DNA.

Concordance rates

The frequency with which one twin is diagnosed with an illness, when his or her twin is also diagnosed with the same illness.

Cortisol

	The hormone that regulates the body's reaction to stress.
<i>Genetic influences</i>	The biological blueprints for behavior that are contained in a person's chromosomes.
<i>Imitation</i>	A theory that states that children may learn to be violent by imitating an adult's aggression.
<i>Minimal brain dysfunction or minimal brain damage</i>	Very low levels of brain dysfunction, theoretically affecting behavior, emotions, learning, or memory.
<i>Neurotransmitters</i>	Chemicals secreted by the brain, some of which have been linked to aggression.
<i>Paranoid misperceptions</i>	Attitudes or belief systems that misinterpret ambiguous circumstances as signs of danger when none actually exists.
<i>Resilient state</i>	The state in which a person is likely to resist developing a disorder.
<i>Serotonin</i>	One of the monoamines, low levels of which have been implicated as related to aggression.
<i>Testosterone</i>	One of the androgens. A male sex hormone that is associated with aggression.
<i>Vulnerable state</i>	The state in which a person is likely to develop a disorder.

Violent crimes can be as baffling as they are repelling. In England, two 10-year-old boys lured a 2-year-old away from his mother at a shopping mall; they took him down to the local railroad tracks, where they beat him to death and left his body to be run over by a train. In the United States, a group of teenagers shot and killed a man whose car they were stealing – even though the man had willingly handed over his car keys and was not resisting the theft in any way. In Massachusetts, a group of young teenage schoolgirls planned to murder their English teacher because she was too strict.

To understand the causes of violence, it is not always enough to understand the external circumstances that often drive other types of criminal behavior. It is true that violence sometimes results from factors such as an individual's desire for financial gain or an individual's repeated exposure to violent behavior in his or her social environments. Sometimes, however, violence also happens in an apparently motiveless fashion. Violence is never truly without motive, but the motives may be so complex and elusive that the violence appears motiveless. In all cases, but particularly in cases of violence that appear to have no motive, internal or individual factors may be critical for understanding the cause of such behavior. A variety of different biological and psychological influences and mechanisms have been considered over the years. This article summarizes

them and attempts to construct a more comprehensive model of the causes of violent behavior.

Types of Biological Influences

There exists a mistaken tendency to use the terms biological and genetic interchangeably. In fact, genetic influences are only one type of biological influences on behavior. There are (at least) two different types of biological influences: genetic influences and biological environmental influences. Genetic influences refer to the blueprints for behavior that are contained in a person's chromosomes. Chromosomes contain deoxyribonucleic acid (DNA), the genetic material a person inherits from his or her biological parents, which is referred to as their genotype. Biological environmental influences, unlike genetic influences, are events that affect a person biologically but that are not encoded into the person's DNA. For example, consider a head injury from a car accident, which subsequently changes the victim's personality. The head injury is unmistakably a biological environmental influence. No genotype determines that someone will have a car accident; however, such an accident, and its accompanying head injury, can still have an important biological effect on the person's behavior.

Although learning is clearly related to violent behavior, learning theories alone cannot fully explain violence in human beings. As an example, consider the principle of imitation. It states that children may learn to be violent by imitating an adult's aggression. According to this principle, one would expect that children who grow up watching violent parents would be violent themselves. As the theory predicts, a higher proportion of children who witness violent parents are violent, in comparison to other children; however, despite their higher risk, many children of violent parents do not, in fact, behave aggressively as adults. Some children who are exposed to violent psychosocial environments do become violent; many other children who are similarly exposed do not. This fact has led researchers to coin the terms resilient and invincible to describe children who survive and cope well despite terrible circumstances.

What makes one child resilient and another child vulnerable? Researchers have identified a variety of differences, including biological differences, that distinguish resilient and vulnerable children. It is important to note that such biological differences do not entirely explain why one child is vulnerable and another is resilient; rather, biology appears to be an important part of the determination. It is reasonable to assume that different biological influences will play

different roles in the determination of vulnerability and resiliency.

One important area that researchers have studied focuses on minimal brain damage. Also called minimal brain dysfunction, minimal brain damage does not look like major brain damage. A person with minimal brain dysfunction will not have obvious brain damage; however, minimal dysfunction may affect behavior, emotions, learning, or memory – that is, the more subtle (or higher) functions of the brain. For example, although major brain damage might result in severe mental retardation, minor brain dysfunction might result in a learning disability that would not necessarily affect intelligence in any way (e.g., dyslexia). It has been repeatedly demonstrated that minimal brain dysfunction is related to problems such as learning disorders and hyperactivity. Those relationships emerged as a rationale for studying a link between minimal brain dysfunction and violence, but how to study such a link is somewhat controversial in the field. Some researchers have examined violent individuals to see if they have high levels of minor physical anomalies, while others have given aggressive and violent men neuropsychological examinations. Still other psychologists have combed through the medical histories of violent individuals, seeking unusually high levels of brain injury in their histories. Although different researchers have taken different tacks, their findings have been consistent. However one chooses to measure minimal brain dysfunction, a host of research suggests that it is indeed related to persistent aggression and violence. Further, although both major and minor brain damage may cause violence, the weight of the evidence suggests that the most important type of brain dysfunction in people who are chronically violent and criminal is minimal brain dysfunction. Although it is almost certain that most people with minimal brain dysfunction will never be violent, a noticeably high number of repeat violent offenders show some level of brain dysfunction (usually minimal).

Neurotransmitters

There are many different types of neurotransmitters, and they tend to specialize in function. How much, or how little, of any particular neurotransmitter chemical is in your brain is an important determinant of many types of behavior. Both biology and psychosocial environment affect the levels of different neurotransmitters, and thus affect behavior. A logical question, therefore, is whether violent behavior is related (at least in part) to the level of certain neurotransmitters in the brains of violent people.

Monoamine neurotransmitters have been most significantly linked to aggression. Of the monoamines,

low levels of serotonin have been implicated most strongly in recent research. Several studies have found consistent relationships between reduced serotonin activity and aggression and hostility in both boys and men. As is often the case in such research, the relationship was strongest among males, regardless of their age. This set of studies is interesting because it establishes such relationships among psychiatrically well patients as well as among behaviorally disordered individuals.

Hormones

Two hormones have been the focus of most research on aggression and criminality: testosterone and cortisol. Testosterone is one of the male sex hormones, called androgens. Both males and females secrete androgens, but males secrete a much greater quantity than females. Androgens are frequently cited as an important cause of aggressive behavior, particularly intermale aggression. This area of study is not completely consistent, however, and while some research points to aggression and dominance/hostility as being related to testosterone, other research fails to find that dominance/hostility measures are related to sex hormones. Some research notes a testosterone–aggression relationship in both males and females; other research finds it only for males. To muddy the waters even further, researchers who follow those experiments involving reduced testosterone functioning do not note that this is a clearly effective means of stopping aggression. In addition, psychosocial researchers suggest that high testosterone might result in kids being treated differently socially, since high testosterone is associated with being bigger and stronger. Androgens, therefore, have been implicated, but not strongly, in the cause of aggression.

A second hormone that has been implicated more recently is cortisol. Cortisol is the hormone that regulates the body's reaction to stress. It is involved with the immune system and with sex hormones as well. A few studies have linked low levels of cortisol with a tendency to be aggressive. Although this should be characterized as an exploratory area of research, it is interesting to note that low cortisol has even been found in females with conduct disorders.

Genetics

The majority of researchers agree that violence does not appear to be a behavioral tendency that is transmitted via a simple, directly acting gene. In any case, it is clear that if genetic bases for aggression and violence exist, they are clearly mutable and changeable by a person's psychological environment; the old idea that genetics determines one's behavior absolutely is clearly mistaken.

The case for genetics as a cause of aggression and adult criminal violence has to be pieced together from a number of different areas of study. First, we know that children with violent parents do have a higher tendency to be violent themselves. Second, data from twin studies show the same trend.

Twin studies are natural genetic laboratories; they are studies that typically compare identical (monozygotic) to fraternal (dizygotic) twins. Identical twins are the only human beings alive who are genetically identical. Some psychological disorders have much higher concordance rates for monozygotic twins. For example, schizophrenia has a concordance rate of 50%; if one identical twin has schizophrenia, then there is a 50% chance that the other twin will also have schizophrenia. Similar, and even higher, rates of concordance for aggressive behavior have been noted among twin pairs.

Despite these family studies finding a reasonably strong genetic link for aggression, some clarification is important. Specifically, the field needs to make the critical distinction between biological heredity versus family psychology. Parents provide a psychological, as well as a biological, environment for their children. Likewise, twin studies fail to tease apart the effects of psychosocial environment and genetics. In addition to sharing genes, twins also often share an environment that treats them similarly.

For this reason, adoption studies (in which a child has one set of biological parents and a different set of psychological parents) may do a better job of teasing apart heredity and psychological environment. Earlier classic studies, which examined children prospectively in long-term studies, found that children seemed to follow their adoptive parents' behavior, rather than their genetic parents (suggesting a stronger link with psychological environment than genetics). More recent research has also found that biological siblings had a higher concordance for aggression, in comparison to adoptive siblings.

Both family studies and adoption studies suggest a definite degree of heritability for aggression, but there is a third body of research that is relevant here: studies that examine the heritability of childhood precursors of violence in adulthood. This body of research examines childhood disorders that are highly related to violence and studies whether these childhood disorders are heritable. For example, attention-deficit/hyperactivity disorder and conduct disorders are both childhood disorders with strong ties to adult violence, and both disorders appear to be at least partially heritable. The heritability of a disorder such as violence may therefore proceed through the pathways of other, co-existing disorders, or, alternatively, some childhood disorders may be precursors to adult

violence in a child who has inherited that behavioral tendency.

In summary, much of the data on the genetic basis of violence is suggestive of a significant, but not total or direct, heritability.

Hostile Interpretation of Ambiguous Events, or Cognitive Distortions

In 1996, a 17-year-old boy attacked a total stranger, unprovoked, with an ax. He knocked on the man's door, and when it was opened he attempted to attack before he was driven off by his intended victim. His defense in court? That he was mentally deranged and unusually paranoid due to late-stage Lyme disease. Before he became ill, this boy apparently had no behavioral problems, but his Lyme disease caused him to develop the unusual, but not unheard of, symptom of paranoid delusional misperceptions.

Cases this like are certainly rare. But are paranoid misperceptions rare among violent individuals? One theory suggests that such biased misperceptions may in fact help explain why some people are violent. Indeed, as the theory goes, under certain circumstances, aggression may be a normal and adaptive response. This may particularly be the case when an individual is faced with hostile or threatening forces, and violence is perceived as a necessary response. Given that a hostile environment might provoke an aggressive response in almost anyone, some researchers have investigated the possibility that violent individuals are not people who inappropriately choose violence; rather, they are people who inappropriately perceive hostility in situations where most people would not. That is, perhaps it is not the response that is skewed, but the perception of the environment.

How do aggressive children perceive the environment, and are their perceptions uniform? Studies find that aggressive children have two perceptual tendencies that nonaggressive children lack. Aggressive children are more likely to believe that other people had hostile intentions, and they are more likely to evaluate the results of aggression positively. Classic research has identified this thought pattern and has found that hostile biases were particularly characteristic of reactive-aggressive children. Researchers have similarly found that aggressive boys are significantly better at recognizing aggressively slanted comments. Studies have noted that children with memories that emphasize hostility process information in a more negatively biased way and are more likely to develop stable negative cognitive biases and stably aggressive behavior.

This line of study sheds some light on why it may be so difficult to treat violent offenders. Trying to teach such offenders to be nonviolent may in fact be trying

to teach them to react nonviolently to what they perceive to be intensely threatening situations. For example, imagine that you are standing in a field holding a gun, and an elephant is charging toward you in a rage at full speed with his tusks aimed right at you. Trying to teach violent offenders to be nonviolent might be like trying to teach them not to shoot that elephant, even though there is every indication that that elephant is deadly.

Other research has examined different types of violent offenders and has found cognitive misinterpretations and biases that appear to be specific to the type of offense. For example, rather than making general, nonspecific hostile misinterpretations, adults who commit child abuse tend to misinterpret children's behavior. Specifically, they tend to regard children's misbehaviors as more intentional than they really are – possibly paving the way to righteous anger and abuse. Sexually aggressive men, rather than suffering from blanket distortions, may differ from other men primarily in their distortion of women's communications. It seems clear that a wide variety of cognitive misperceptions seems to pave the way for a variety of different types of aggressive and violent behavior, and may help explain the difficulty of effectively treating such behavior.

Summary

Strong evidence exists to support the theory that individual differences can affect a person's risk for developing chronically violent behavior. These risks appear to interact with psychosocially learned factors and

may differ significantly from individual to individual. The mechanism by which these associated risk factors contribute to violence is less well established. Research has identified heritability, hormones, minimal brain dysfunction, and biased cognitive misperceptions as likely areas of dysfunction related to violence and aggression. Future research will focus on effective prevention efforts and a better understanding of how risk factors influence individuals' behaviors.

Glossary

Apoptosis

Programmed cell death that occurs in an orderly fashion, following a preexisting pathway and in response to specific inducers.

Caspases

A family of enzymes essential for apoptosis; these enzymes carry a cysteine that is key for cleaving proteins after an aspartic acid residue.

<i>Endoplasmic reticulum (ER)</i>	An organelle of the eukaryotic cell formed by a single membrane, which is an extension of the inner membrane of the nuclear envelope. The ER membrane is folded onto itself around a space, the lumen, which is in direct communication with the intranuclear space.
<i>ER stress</i>	Cellular stress at the level of the endoplasmic reticulum; may be caused by viruses.
<i>Golgi apparatus</i>	An organelle of the eukaryotic cell present in plants and animals (although not in the cells of most fungi). Its chief functions are protein processing and sorting; also called the Golgi body or Golgi complex.
<i>Mitochondrion</i>	A eukaryotic cell organelle present in most organisms. The mitochondrion's primary role is the conversion of fuel, in the form of organic materials, into energy, in the form of ATP. Mitochondria interact with the ER, particularly in situations leading to apoptosis.
<i>Molecular chaperone</i>	A large group of special proteins that play an essential role in protein homeostasis. They are in charge of maintaining the entire complement of proteins in all cells and cellular compartments in their native functional conformations. The chaperones residing in the ER are particularly relevant to viral infection and its consequences for the cell through the induction of the unfolded protein response.
<i>Necrosis</i>	Uncontrolled cell death; the consequence of acute, unanticipated cell or tissue injury.
<i>Programmed cell death</i>	A controlled mechanism of cell elimination by suicide that multicellular organisms possess.
<i>Signal transduction</i>	The cellular process of converting one kind of signal or stimulus into another. This process is usually very fast and involves a series of intracellular biochemical reactions in a specific sequence, signaling cascade, requiring specific enzymes and second messengers.
<i>Unfolded protein response (UPR)</i>	A series of events that starts with the accumulation of unfolded, partially folded, misfolded, or aggregated proteins in the ER lumen, which triggers ER stress, inhibiting the functions of the organelle. This emergency situation then requires immediate action, which is mediated by the signal transduction cascade and results in the upregulation of some genes and in the downregulation of other genes.
<i>Virulence</i>	The capacity of an infectious agent (e.g., a bacterium or a virus) to invade a host and cause lesions and disease.

Virus A biological particle that contains nucleic acid and other components, such as proteins and lipids, assembled in a shape that is typical for each viral species. A chief characteristic of viruses is that they require a host cell in which to replicate.

Many viruses cause cellular stress at the level of the ER (ER stress) and elicit the unfolded protein response (UPR). The main causative event is the accumulation of unfolded and/or misfolded proteins inside the ER; this accumulation immediately activates signal transduction pathways directed toward the nucleus, causing the upregulation of some genes and downregulation of others. This increases the proteins necessary to deal with stress in the ER while reducing many nonessential proteins, thereby lessening the task of processing them as it would under normal circumstances. If the ER burden is overwhelming, beyond mitigation, cell death occurs via apoptosis. Viruses control these processes to ensure that the cell will not die until they have replicated in sufficient numbers to achieve efficient propagation upon cell disintegration following apoptosis.

Scope

Viral infection has an impact on various biological functions at the level of the whole organism and at the levels of organs, tissues, cells, subcellular structures, molecules, and genes. Thus, the topic of viral virulence and stress can be treated from a variety of perspectives, centering on the immune system, the endocrine system, the gastrointestinal tract, the blood and blood-forming tissues, or many other systems and tissue and cell types. Moreover, the approach to the subject matter considered here can also be diverse, for example, clinical, histopathological, cytological, subcellular, and molecular. We focus on the cell of eukaryotic multicellular organisms (e.g., humans and rodents) and discuss the impact of viral infection on the ER, specifically virus-induced ER stress, the ensuing UPR, and the ER molecular chaperones.

Viral Infection and ER Stress

A number of viruses are known to cause ER stress and to induce the UPR (Table 1). These viruses are of interest because they are pathogenic to humans and to animals valuable to humans. Some of these viruses cause very serious diseases. For example, hepatitis C virus (HCV) causes hepatitis that can develop into liver cirrhosis and then into hepatocellular carcinoma. Others, such as the human cytomegalovirus (HCMV), cause mild illnesses in otherwise healthy individuals,

Table 1 Some viruses that cause ER stress and trigger the UPR^a

Name	Family	Subfamily	Genus	Group	Nucleic acid	Pathology
HCV	Flaviviridae	–	<i>Hepacivirus</i>	IV	ssRNA(+)	Non-A non-B hepatitis, liver cirrhosis, hepatocellular carcinoma
Bovine viral diarrhea virus	Flaviviridae	–	<i>Pestivirus</i>	IV	ssRNA(+)	Diarrhea in cattle
Japanese encephalitis virus	Flaviviridae	–	<i>Flavivirus</i>	IV	ssRNA(+)	Encephalitis
HCMV or HHV-5	Herpesviridae	β -Herpesvirinae	<i>Cytomegalovirus</i>	I	dsDNA	Infectious mononucleosis, retinitis, serious infections in people with defective or immature immune systems ^b
HHV-1/ HSV-1	Herpesviridae	α -Herpesvirinae	<i>Simplexvirus</i>	I	dsDNA	Oral and genital herpes
EBV or HHV-4	Herpesviridae	γ -Herpesvirinae	<i>Lymphocryptovirus</i>	I	dsDNA	Infectious mononucleosis, Burkitt's lymphoma
HRSV	Paramyxoviridae	Pneumovirinae	<i>Pneumovirus</i>	V	ssRNA(–)	Respiratory tract infections
TULV	Bunyaviridae	–	<i>Hantavirus</i>	V	ssRNA(–)	Hemorrhagic fever ^c
Murine retroviruses	Retroviridae	–	Several	IV	ssRNA-RT	Tumors and leukemias in mice

^ads, double-stranded; EBV, Epstein–Barr virus; ER, endoplasmic reticulum; HCMV, human cytomegalovirus; HCV, hepatitis C virus; HHV-1/HSV-1, herpes simplex virus 1; HHV-4, human herpes virus 4; HHV-5, human herpes virus 5; HRSV, human respiratory syncytial virus; ss, single-stranded; TULV, tula hantavirus; UPR, unfolded protein response.

^bFetuses, newborns, immunosuppressed individuals; and AIDS patients.

^cChiefly affected are the kidneys, lungs, and heart.

but they can cause very serious infections and even death in immunocompromised individuals (e.g., a patient who has received an organ transplant and is undergoing immunosuppressive therapy to prevent rejection of the transplanted organ). Still other viruses cause non-life-threatening but troublesome lesions; for example, herpes simplex virus 1 (HSV-1) produces painful blisters (herpes) of the oral cavity and lips.

Chain of Events and Its Consequences for the Virus and for the Infected Cell

It is important to realize that although a viral infection has a direct impact on the ER, it also affects other organelles, particularly the Golgi apparatus. Furthermore, it affects not only the originally infected cell but also many others in the vicinity and in tissues far away from the original infection site.

Another important consideration is that viral infection, viral virulence and its impact on the cell (the ER in particular), induction of the UPR and apoptosis, and cell destruction must all be regulated so the virus can multiply and propagate to other cells and tissues. If the damaging impact of the viral infection on the cell is too strong and too fast, the cell will die too soon for the virus to complete its cycle of infection and replication and the cell will disintegrate before a

sufficient number of viral particles have been assembled for efficient propagation to other cells and organs via the blood.

Viruses need the host cell – its genes, proteins, and structures – for the replication and assembly of progeny virus. Thus, evolutionarily successful viruses have acquired genes and mechanisms that allow them to use the host cell's assets, even as they trigger ER stress and the UPR, en route to apoptosis. Some of the genes acquired by viruses for controlling the cellular response to infection encode anti-apoptotic proteins, which temporarily counteract the action of pro-apoptotic factors that are produced by the host cell on viral infection.

The Endoplasmic Reticulum

Subcompartments

Although the ER is a single organelle, present in one copy per cell, it includes specialized subcompartments, or domains, with specific functions.

- The rough ER (RER) is in contact with associated ribosomes, is close to the nucleus, and is involved in protein synthesis and in the translocation of newly synthesized polypeptides from the cytosol into the ER lumen.

- The transitional ER (tER) appears as cup-shaped cisternae and is involved in the exit of newly made polypeptides carried in coat protein complex II (COPII) vesicles toward the secretory route.
- The smooth ER (SER) participates in calcium storage, in lipid and steroid synthesis, and in the breakdown of drugs and chemical compounds, such as those present in medical remedies, which occurs predominantly in liver cells. The SER involved in calcium storage is prominent in muscle cells, including those of the heart and limbs; thus the SER plays a key role in muscular contraction, namely body movements and heart beats.

The Endoplasmic Reticulum is a Highly Dynamic Organelle

The ER varies quantitatively and qualitatively from cell to cell, depending on the functional status of the cell and on the tissue or organ in which the cell resides. Likewise, the distribution of the ER subcompartments inside a cell varies in relation to the cell-cycle stage and functional phase. For example, SER usually occurs in relatively small quantities, but its abundance is greater in cells that process and secrete lipids or steroids (e.g., in adrenal gland cells actively producing steroid hormones). RER is very abundant in cells that actively synthesize proteins, such as digestive enzyme-producing cells in the glandular tissue lining some portions of the gastrointestinal tract, and in plasma cells that actively produce immunoglobulins.

Specialized ER subcompartments also change within a cell, as illustrated by the switch from SER to RER, and *vice versa*; such a transition occurs in cells switching from low to high rates of protein synthesis, followed by return to the initial resting phase.

The Endoplasmic Reticulum and the Golgi Apparatus

Another important organelle of the eukaryotic cell is the Golgi apparatus, which interacts continuously with the ER. The Golgi is built of vesicles, tubules, and cisternae piled close to one another. All of these structures are formed by membranes composed of a huge range of proteins, perhaps well over a 1000 different varieties of proteins. The Golgi also possesses an enormous capacity for morphological transformation. This dynamism of the Golgi is affected by many factors, such as cellular environmental conditions, the cell's mitotic and physiological stages, the presence of drugs, stressors, disruption of microtubules, and protein movement from the ER.

The unusual plasticity of the Golgi membranes is probably due to the fact that proteins associate with the membrane only temporarily while they are

traveling from the ER to other cellular locales. In fact, no specific class of protein has been identified that is uniquely and permanently part of the Golgi membranes. Golgi components are continuously entering and exiting this organelle.

The Golgi apparatus participates in protein glycosylation, cleavage of preproteins to produce the active form of the protein, and sorting of molecules so that they are properly tagged and thus directed to their physiological destinations, whether the cytosol, the cell membrane, or the extracellular space. The number of copies of the Golgi apparatus per cell varies from one to many, according to cell type, cell location (tissue type), and physiological and cell-cycle stage.

The Golgi can be subdivided into several regions, on the basis of function. The cis region lies near the ER and the nucleus and receives vesicles with their cargo of molecules coming from the SER. The middle region is the site of protein and lipid processing (e.g., glycosylation), and the trans zone or network region is sited near the cell membrane. In this region of the Golgi, preproteins are cleaved to generate functional protein molecules (as part of the maturation pathway from nascent polypeptide to fully processed, native protein) and the fully processed proteins are sorted according to their final destinations.

Interaction of the Endoplasmic Reticulum with Other Cellular Structures

The ER communicates directly with the nucleus, as mentioned earlier. Likewise, the ER (in the tER regions) interacts with or is modified by mitochondria, mRNAs, plasma membrane, peroxisomes, and phagosomes. These structures affect, from the outside, the shape and functionality of the ER, generating the various regions of this organelle, which suggest at first glance a variety of different ERs. Important within the context of this article is the interaction of the ER with mitochondria, a key stage in apoptosis.

Stress Proteins and Molecular Chaperones in the Endoplasmic Reticulum

A set of molecular chaperones resides and functions in the ER ([Table 2](#)). The ER chaperones participate in protein folding, refolding, and degradation, as do chaperones in other cellular compartments. However, the ER chaperones are involved as well in other processes that are unique to this organelle, such as calcium binding and protein translocation (exit from and entry into the ER lumen). It is of interest that some of the genes encoding ER chaperones are induced by glucose deprivation, which explains why these chaperones are classified and named as glucose-regulated proteins (e.g., Grp78, for glucose-regulated protein 78; see [Table 2](#)).

Table 2 Some stress proteins and chaperones found in the endoplasmic reticulum^a

Mass (kDa)	Examples ^b
100 or higher	Hsp170 (Grp170)

^aStress proteins are those whose parent genes are induced by stress caused by any stressor. However, not all stress proteins are molecular chaperones; likewise, not all chaperones are stress proteins. Examples of chaperones residing in the ER are listed, whether or not they are stress proteins. There are also many other stress proteins in the ER (not listed here) that are not chaperones or that are not known at this time to function as chaperones.

^bSynonyms are given in parentheses. Chaperones build multimolecular assemblies in order to exercise their functions. These assemblies are formed by identical or different chaperone molecules (subunits) and cofactors. In addition, these chaperone complexes interact with other chaperone complexes (networking) and with the protein-degradation machinery (e.g., the ubiquitin-proteasome system) to integrate the protein quality-control system of the cell.

The importance of the ER chaperones, both in normal physiological events and in dealing with stress generated by a variety of stressors (including viruses), emphasizes the critical, deleterious effects that defective chaperones have on the cell, and on the organism in general. A newly recognized type of pathology, the chaperonopathy, encompasses chaperones that are abnormal due to genetic (e.g., mutation) or acquired (e.g., aberrant posttranslational modification) defects and the impact of such abnormal chaperones on health and disease. The consequences of a chaperonopathy in the ER have not yet been evaluated, but they can be predicted to be significant for the cell and for any virus that causes ER stress. It is likely that chaperone molecules become deficient with age, due to the same biochemical modifications that affect other proteins in the elderly; thus, the probability that viral infections will cause serious ER stress and cell damage is likely to increase with senescence.

ER Stress

A variety of stressors, including certain viruses (Table 1), can cause ER stress and can trigger the ER-stress response. This variety of stressors notwithstanding, the common central factor underlying ER stress is

the presence in the ER lumen of denatured proteins – partially or totally unfolded, or misfolded proteins. It is crucial for survival that, under ER-stress conditions, the cell readjusts a series of mechanisms that will reduce the number of ER tasks (essentially by diminishing the number of peptides that travel through and are modified in the ER) while increasing its functional power by expanding the ER's capacity to modify and tag proteins and to assist them in folding and refolding, thus steering them toward a productive pathway.

The ER plays a critical role in the monitoring of protein quality as the molecules traverse the organelle. It possesses the means to detect and to correct aberrant peptides and abnormal protein conformations. However, if correction is impossible, the ER has mechanisms to lead unrecoverable peptides toward degradation via the ER-associated degradation (ERAD) pathway. Finally, if all else fails, the ER can steer the cell toward apoptosis.

In addition to protein folding and modification (e.g., glycosylation), the synthesis of lipids and sterols occurs in the ER. Recent data suggest that lipid synthesis is altered as much as protein quality control during ER stress and the ensuing UPR.

A key event in the UPR is the increased expression of the genes encoding the ER-resident chaperones (Table 2). When the ER is overwhelmed by an excess of too many bad proteins, signals travel from the organelle to the nucleus, resulting in the upregulation of some genes and the downregulation of others. The downregulation reduces the nonessential biosynthetic tasks (e.g., tasks pertaining to the synthesis of secretory proteins) of the ER, which must redirect its resources to deal with stress. Still other mechanisms, such as the inhibition of mRNA translation, cooperate in reducing the synthesis of nonessential proteins.

ER Stress and Apoptosis

Apoptosis, a form of programmed cell death, is a multistage process that involves various types of molecules, many of them enzymes. The series of stages – the apoptotic cascade – can be induced in various manners that may schematically be organized into two main pathways: intrinsic and extrinsic. Intracellular injury (e.g., DNA damage and ER stress) starts the intrinsic or ER-stress apoptotic pathway, whereas extracellular agents activate the extrinsic (or receptor-mediated) pathway. In the latter pathway, the initial steps require the participation of cell-surface receptors to engage the enzyme caspases (cysteiny aspartic acid proteases) and start the caspase cascade. This cascade includes the caspase-8-dependent cleavage of caspase-3 and the participation of caspase-8 in the cleavage of Bcl-2-associated

protein 31 (Bap31; Bcl stands for B-cell leukemia), and the recruitment of Bcl-2 proteins that interact with mitochondria and cause the leakage of cytochrome c from the organelle into the cytosol. This is followed by formation of a caspase-9 complex and apoptosis.

In contrast, the intrinsic pathway involves the mobilization of caspase-12 with the direct activation of caspase-9, initially bypassing the mitochondria. However, the intrinsic pathway also involves mitochondria (and cytochrome c leakage) through Bap31 cleavage with participation of caspase-12, resulting in the amplification of the caspase cascade.

Bcl-2 homologous antagonist/killer (Bak) and Bcl-2 associated X (Bax) proteins (i.e., two members of the pre-apoptotic class of proteins) become inserted into the ER membrane at the beginning of the ER-stress pathway, causing calcium efflux, which in turn causes an increase in cytosolic calcium. Calpain is activated, as is procaspase-12 in the ER. The caspase cascade proceeds up to the activation of procaspase-3. At this junction, there is no involvement yet of apoptotic protease-activating factor-1 (Apaf-1; a component of the apoptosome, whose main components are Apaf-1, cytochrome c/dATP, and procaspase-9), nor is there leakage of cytochrome c from the mitochondria into the cytosol. While the apoptotic cascade progresses, cytosolic calcium is taken up by the mitochondria as it escapes from the ER and mitochondrial membrane pores open, allowing cytochrome c to pass into the cytosol. At this point, the apoptosome is assembled and becomes active, as does procaspase-3.

The extrinsic route to apoptosis involves other factors: the c-Jun N-terminal kinase (JNK) inhibitory kinase (JIK), tumor necrosis factor receptor-associated factor 2 (TRAF2), and inositol-requiring enzyme 1 α (Ire1 α or IRE1 α). A trimeric complex is assembled that includes IRE1 α , TRAF2, and apoptosis-signal regulating kinase 1 (ASK1), resulting in the activation of ASK1 and JIK. This is followed by cell death.

The intrinsic and extrinsic pathways interact. TRAF2 promotes procaspase-12 aggregation and is released from procaspase-12 when ER stress occurs. This may happen because TRAF2 sequesters IRE1 and thus activates procaspase-12.

Some of the steps just described require additional experimental confirmation. Although these apoptotic pathways require caspases, suicide in some cells (e.g., certain neurons) does not involve these enzymes but resort to other mechanisms. In general, no matter which pathway is considered, caspase-dependent or -independent, the details of the mechanisms involved are still incompletely understood and may vary among cell types. However, the data available do indicate that the intrinsic and extrinsic apoptotic routes

intersect and that the ER is at center stage in the programmed cell death triggered by ER stress.

ER Stress and Viral Infection: Examples

Hepatitis C Virus

HCV, a single-stranded RNA virus, causes non-A non-B hepatitis in humans. The potential consequences of the viral infection are the development of hepatic cirrhosis and eventually hepatocellular carcinoma. The ER is the site of HCV core processing and maturation; these processes involve the interaction of viral components with the ER membrane.

We have seen that the UPR is characterized by the activation of signals from the ER to the nucleus, resulting in the increased expression of ER-chaperone genes, calcium-binding proteins, and sarcoplasmic-ER calcium-transporting ATPase 2 (SERCA2), whose function is to pump calcium from the cytosol into the ER. In contrast, other proteins are decreased, via either the downregulation of their parent genes or the inhibition of the translation of their mRNAs. In this process, double-stranded-RNA-activated protein kinase-like ER kinase (PERK) plays a role, by mediating the phosphorylation of the eukaryotic initiation (of translation) factor 2 α (eIF2 α). When ER stress is intense and/or prolonged, apoptosis can occur in one of the following ways, depending on the animal species and other factors: (1) the activation, in mouse cells, of caspase-12 (not yet found in humans); (2) the activation of the C/EBP-homologous protein (CHOP; also known as the growth arrest- and DNA-damage-inducible gene 153, GADD153); or (3) the induction of JNK, involving a complex formed by TRAF2 and ASK1.

Calcium signaling is also dependent on ER function. The ER controls the opening of the inositol 1,4,5-triphosphate receptor (IP3R) channels and calcium uptake into the lumen by the SERCAs. The mitochondrion also participates in calcium trafficking; this organelle is very efficient in calcium uptake and release. Some mitochondria are situated very close to the ER and thus are conveniently positioned to sense changes in calcium concentration in the cytosol as luminal calcium leaks out of the stressed ER through activated calcium (IP3R) channels.

The HCV core induces the expression of the chaperones BiP(Grp78), Hsp90(Grp94), and calreticulin (Table 2) and SERCA2 at levels well above those characteristic of the unstressed ER. The increase in the levels of all these proteins is enhanced and paralleled by the loss of calcium from the ER lumen. Eventually, the HCV core triggers the apoptotic cascade due to the hyperexpression of CHOP/GADD153

(which acts as a pro-apoptotic factor), Bax translocation to mitochondria, mitochondrial membrane depolarization, cytochrome c efflux, and caspase-3 activator and poly-(ADP-ribose) polymerase (PARP) cleavage.

Human Cytomegalovirus

HCMV belongs to the Herpesviridae family, along with the varicella-zoster virus, HSV-1, and HSV-2, which cause chickenpox and shingles, and Epstein-Barr virus (Table 1). Epstein-Barr virus and HCMV are the most common etiological agents of infectious mononucleosis. HCMV remains dormant in infected cells without generating symptoms, but it can be activated and can generate serious cell injury in individuals with immature immune systems (e.g., fetuses, newborns, and patients with congenital deficiencies), and in patients with impaired immunity, such as those being treated with drugs that kill lymphocytes and other blood cells (e.g., cancer patients undergoing chemotherapy and individuals who have received an organ transplant and are being given immunosuppressants to prevent rejection of the foreign tissue).

HCMV induces ER stress, which is sensed by means of activating transcription factor 6 (ATF6), PERK, and IRE1. Normally, in the absence of stress, BiP(Grp78) (see Table 2) is bound to each of the sensors on the luminal side of the ER membrane. If unfolded, misfolded, or aggregated proteins accumulate in the ER, BiP(Grp78) releases the sensors and interacts with the proteins to assist them to fold correctly so that they can regain their native functional conformation. When PERK and IRE1 are no longer bound to BiP(Grp78), their luminal domains form homodimers and become phosphorylated and activated. Simultaneously, ATF6, also freed from the chaperone, exposes a Golgi localization signal on its structure and is thus translocated to the Golgi, in which it is cleaved and activated.

PERK activation initiates a pathway for the attenuation of translation that involves eIF2 α , eIF2 β , activating transcription factor 4 (ATF4), and other gene proteins. At the same time, ATF6 mediates transcriptional upregulation of ER chaperone genes. ATF6 is an ~50-kDa protein produced by the digestion of a 90-kDa preprotein in the Golgi. As a result of the ATF6-initiated pathway, the levels of ER chaperones increase in response to the increased demand due to accumulation of client polypeptides in the ER lumen.

Also part of the virus-initiated UPR is the induction of the IRE1 pathway, increasing the expression of genes whose protein products are involved in promoting protein degradation. In this manner, defective peptides that cannot be refolded by the chaperones are

eliminated via digestion, and the digestion-derived amino acids are reused on the ribosome to synthesize essential proteins (e.g., chaperones) as required by the increased demand due to ER stress.

In summary, HCMV intervenes in the regulation of the three routes of signal transduction characteristic of the UPR, the routes mediated by PERK, IRE1, and ATF6. The HCMV intervention ensures that the virus has time to replicate while the cell is preparing for apoptosis, which leads to cell disruption and the release of viral particles. In this regard, it has been found that the genes encoding ER chaperones are also induced by the virus independently of the ATF6-initiated pathway, possibly because the chaperones are needed for the generation of proteins required by the virus. In parallel, the protein degradation ER degradation-enhancing 1,2-mannosidase-like (EDE1) factor was found to be inhibited, so as to transitorily curtail proteolysis and thus ensure the presence of the molecules necessary for cell survival during viral replication.

Stress and Viral Reactivation

Viral infection causes cell stress, as just explained. The reverse, the stress activation of latent viruses, also occurs. Some viruses become latent after the acute phase of infection; their presence in the cell causes no clinically detectable effects. The viral genome remains in the infected cell but is transcriptionally repressed except for a minor region; hence the virus is inactive or latent. A number of cell stressors, such as fever, ultraviolet light, and social tensions, with their accompanying neuroendocrine imbalance, induce the reactivation of these latent viruses. Viruses belonging to the Herpesviridae family (Table 1), (e.g., HSV-1, varicella zoster virus, and Epstein-Barr virus) are among those that pass through active and latent stages depending on the microenvironmental cellular conditions. Upon the impact of stressors, the mechanisms that keep the viral genome transcriptionally repressed are disrupted and the virus begins to replicate and accumulates in the host cell, usually generating pathological and clinical consequences. For instance, when HSV-1, a neurotrophic virus (it invades neurons), is reactivated in ganglionic cells, viral particles are produced, which emerge from the host cell and invade other cells that thus suffer viral-induced stress. The molecular mechanisms that control latency and reactivation are poorly understood. Likewise, the molecular mechanisms that mediate stress-induced viral reactivation have not been fully elucidated and the role of molecular chaperones in these reactivating mechanisms remains to be determined.

Introduction

Stress: Viral Infection and Penetration to the CNS

Cold Stress Neuroinvasiveness and Virulence of Attenuated
WNV

Summary

Glossary

<i>Attenuated West Nile Virus (WNV)</i>	A virus that has lost its neuroinvasiveness but not its neurovirulence.
<i>Blood-brain barrier (BBB)</i>	Property of endothelial cell brain microvessels that provides a barrier for transport of molecules from the systemic circulation into the brain. The BBB is considered to have an important function that provides the central nervous system with a constant environment needed for normal brain function. Stress conditions disrupt the BBB permeability, which is often increased in many stress situations.
<i>Glucocorticosteroids (GCS)</i>	Organic lipid molecules produced primarily in the adrenal gland. GCS serve as local and systemic hormones and act on specific receptors that activate multiple genes and signaling pathways governing multitude biological actions. Most prominent in GCS action are glucose, protein, and lipid metabolism, regulation of immune and inflammatory cells and mediators, bone and muscle remodeling, as well as central nervous system effects.
<i>Neuroinvasiveness</i>	Ability to penetrate the central nervous system.
<i>Neurovirulence</i>	Ability to establish a lethal infection within the central nervous system.
<i>Plaque-forming unit (PFU)</i>	A standard measure of viral load.
<i>Viral encephalitis</i>	Viral infection of the brain. In order to cause encephalitis when invading the central nervous system, the virus must possess neurovirulence.
<i>Virulence</i>	Ability of a virus to cause clinical disease and potential for mortality. Wild-type

West Nile virus is both neurovirulent and neuroinvasive.

West Nile Virus (WNV)

The etiologic agent of West Nile fever, an endemic viral disease in many subtropical regions and an emerging mosquito-borne disease in the United States. WNV is a neuroinvasive flavivirus that may cause systemic and central nervous system infection, paralysis, and death.

Introduction

Stress is defined as any external or internal stimuli that disrupt the natural homeostasis of the organism. Stress situations commonly result in suppression of the immune system. The reaction of the organism to stress can be adaptational and helpful in restoring optimal homeostasis to maintain the organism functions or can lead to a variety of aberrant emotional and physical conditions with long-lasting consequences.

The effect of stress on the humoral immune response has been reported in numerous studies. The responses to stress vary greatly depending on the stress patterns (type and duration) and the type of stressor. The effect of stress on the immune system in human and animal studies is invariably suppressive, on both the cellular and humoral levels.

Physiological responses to stressors are largely mediated by the sympathetic nervous system and the hypothalamic-pituitary-adrenal (HPA) axis. Glucocorticoids (GCS) are major mediators in the reaction to stress and in stress-induced immunosuppression.

Stress stimuli affect the immune system and cause immunosuppression through involution of lymphoid organs, possibly mediated by increased activity of the pituitary-adrenocortical axis. There is also a clear connection between stress, the central nervous system (CNS), and the immune response. The role of the CNS in immune responses to stress conditions associated with infectious viral conditions is also well established. Glucocorticoids released in response to stress are the major mediators of the effect of stress on viral replication, change in virulence, and viral penetration to the CNS.

Stress: Viral Infection and Penetration to the CNS

A variety of stress paradigms have been shown to exacerbate the effects of several infectious agents, including herpes simplex virus, coxsackie B1 virus,

vesicular stomatitis virus, cytomegalovirus (CMV), influenza virus, encephalitic viruses, and mengovirus. Viruses are known to flourish in the stressed host, with increased morbidity and mortality. It appears that stress acts by enhancing virus replication in lymphocytes as shown in the spleen of stressed mice. Since activated lymphocytes can pass through the blood-brain barrier (BBB), the larger fraction of infected lymphocytes in stressed mice could also contribute to higher virus titer in the brain. This possibility, however, awaits further clarification by more direct evidence on the mode of immune cell penetration into the CNS.

An attenuated strain of West Nile virus (WNV) in mice had little capacity to induce encephalitis and death, as the level of the virus in the brain was very low. Specifically, brain virus levels in control mice inoculated with WN-25, a noninvasive variant of the West Nile virus, or SVN, a neurovirulent, noninvasive Sindbis virus, showed titers of less than 2 log 10 plaque-forming units (PFU), whereas the virus titers in the brain of cold-stressed mice or mice exposed to GCS treatment were 8.5, 7.8, and 7.5 (log 10 PFU) for WN-25 and 7.3, 7.1, and 7.0 (log 10 PFU) for SVN, respectively. In stressed mice, these viruses (WN-25 and SVN), both lacking neuroinvasive properties in control nonstressed mice, readily invaded the brain and proliferated to high titer levels ($>10^6$ PFU/brain) in all moribund mice inoculated with WN-25 or with SVN, on top of a stress condition. It was suggested that the neurovirulent properties of non-neuroinvasive viruses can serve as a marker for BBB permeability and aid in studying pathological processes of the brain.

Cold Stress Neuroinvasiveness and Virulence of Attenuated WNV

In mice inoculated with the wild-type strain of WNV, it was shown that short-term exposure of the mice to cold water ($1 \pm 0.5^\circ\text{C}$) for 8–10 days increased the mortality from 47% in control to 92–100% in the cold-stressed mice. Cold or isolation stress increased blood, spleen, and brain virus levels by two to three orders (100- to 1000-fold) as compared to control nonstressed mice. WNV, which was isolated from the brain of moribund stressed mice, was more virulent when inoculated intraperitoneally to normal nonstressed mice. Concomitantly, lymphoid organs such as spleen diminished in mass in the stressed mice. These observations were also demonstrated with WN-25 and SVN.

Since GCS levels are elevated during stress, the effects of stress or corticosterone (a rodent GCS)

injection were investigated on neurovirulence and encephalitis by the attenuated arboviruses. These two viral strains were exposed to the same cold stress paradigm described previously. The stress paradigms induced mortality of 65, 80, and 50% (WN-25) and 75, 78, and 58% (SVN) in cold, isolation, and corticosterone-treated mice, respectively. No mortality was seen in nonstressed virus-inoculated mice. The level of WN-25 virus in the brain of stressed mice was 7.5–8.5 log 10 PFU. No virus was detected in nonstressed inoculated mice. Isolation of a neuroinvasive strain from brains of stress-exposed mice suggested that the induction of infection was attributed to immunosuppression with subsequent increased viral replication and selection of neuroinvasive strain. The WN-25 virus extracted from the brain of moribund stressed mice was extremely virulent; inoculation of as little as 5 PFU to normal nonstressed mice caused severe encephalitis and death. WN-25 showed a change in its neuroinvasive properties, raising the possibility of stress-enhanced proliferation and a selective process leading to reversal of the neurovirulence. In contrast, brain SVN virus levels isolated from moribund mice (stress exposed) were no different from levels of viruses in the nonstressed mice, suggesting a different role of stress in the mechanism of stress-induced virulence.

The susceptibility of stressed mice to the viral infection could be explained by reduced number and suppression of macrophage and T-lymphocyte activity as well as by decreased natural killer cell cytotoxicity. Therefore, stress can induce elevated viremia for longer periods, facilitating the penetration of viruses into the CNS.

Summary

There is strong evidence for an association between stress and the immune system and between the immune system and the CNS. Susceptibility to infections is presumed to be primarily mediated by immune function. Since WNV is widely distributed and is capable of endemic spread, the effect of stress on WNV infection has been studied. It seems that suppressed immune response during stress, with defective function of macrophages and lymphocytes, leads to enhancement of viral replication in the blood and peripheral organs, induction of a selective process, and selection of a neuroinvasive strain.

Glossary

<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	The hormonostatic endocrine axis that regulates cortisol production and secretion.
<i>Lipoprotein lipase</i>	The rate-limiting enzyme that cleaves one fatty acid from a triacylglycerol.

Various techniques are available for the assessment of body composition. These techniques comprise use of anthropometric measurements, radiographic techniques, and more complex techniques such as total body potassium and tetrapolar bioelectrical impedance analysis.

The double thickness of the epidermis and subcutaneous fat is determined by a skin-fold measurement. The skin-fold thickness can be measured wherever a fold can be formed, but specific sites such as the triceps and subscapular locations have been designated because of their high correlations with total body fat.

Body circumferences, like skin folds, can be measured at various body locations. The sites for circumference measurements that have been reported

to be important in describing the amount of abdominal, visceral obesity are the waist and hip circumferences and their ratio, waist–hip ratio (WHR). In addition, the WHR has been reported to be a powerful predictor of obesity-related diseases such as cardiovascular disease, diabetes mellitus, hypertension, and hyperlipidemia. Although the abdominal fat distribution pattern is more common in men, both men and women show increased risk of serious disease with greater abdominal fat. Men may be considered at increased risk if the WHR is greater than 0.95, and women if the WHR is greater than 0.80.

Cortisol regulates adipose-tissue differentiation, function, and distribution, and in excess, causes visceral obesity. The presence of a continuously changing and sometimes threatening external environment may, when the challenges exceed a threshold, activate the hypothalamic-pituitary-adrenal (HPA) axis. The resulting increase in circulating cortisol directs body fat to visceral depots, mainly because of the high density of glucocorticoid receptors in visceral adipose tissue. Thus, central obesity may be regarded as a sign of frequent repeated or chronic perceived stress of various origins, including socioeconomic and psychosocial disabilities, alcohol, tobacco, depression, and anxiety.

Waist–Hip Ratio

Body circumferences and their ratios are used to indicate the distribution of body fat. The most important variations, in terms of health associations, are between the amounts of fat in internal, mainly intra-abdominal sites, as distinct from subcutaneous sites. The ratio of waist–hip circumferences was the first anthropometric method developed from epidemiological research as an indicator of fat distribution in relation to metabolic diseases. Most of the value in indicating body fat is derived from waist circumference, the hip circumference probably reflecting several other body tissues such as bones and muscles.

Waist-Hip Ratio as a Risk Factor

There is a well-documented sex dimorphism in regional adipose tissue distribution. Indeed, despite the fact that women are usually more obese as a group than men, male subjects more frequently have significantly higher mean waist circumference and higher mean WHR in agreement with the greater propensity of men to accumulate excess fat within the abdominal cavity. Since the WHR has been shown to be associated, albeit moderately, with the amount of abdominal visceral adipose tissue measured by computed tomography or magnetic resonance imaging, this index has been widely used to investigate the relations between regional adipose tissue distribution and metabolic profile. Thus it was effective in predicting aberrations in glucose and insulin levels and also showed a strong correlation between plasma lipids and blood pressure. WHR predicted subsequent diabetes in men and coronary heart disease in both men and women, and was more predictive of these endpoints than either the body mass index (kg m^{-2}) or a more complex procedure using the sum of multiple skin-fold thicknesses.

Visceral Adipose Tissue

Adipose tissue is specialized connective tissue that functions as the major storage site for fat in the form of triglycerides. Visceral adipose tissue has a high cellular density as compared to subcutaneous fat. In addition, the blood flow and innervation are more abundant than in subcutaneous adipose tissue. This makes the visceral adipose tissue highly metabolically active, with a turnover of fat that is considerably higher than in other fat depots. This is exaggerated by the high density of specific receptors for steroid hormones, which permit a powerful effect of triggering hormones for adipocyte metabolism, such as catecholamines. Insulin plays a predominant role in the lipogenic process. The net effect of insulin is to enhance storage and block mobilization and oxidation of fatty acids. Insulin exerts its effect by stimulating the formation of lipoprotein lipase (LPL), so that circulating triglycerides are hydrolyzed and free fatty acids can enter adipocytes. Insulin is also required for the transport of glucose, which is needed for re-esterification of triglycerides once inside adipocytes. Finally, the conversion of glucose to fatty acids is accomplished by activation of several enzymes by insulin. Cortisol in the presence of insulin stimulates, via the high density of glucocorticoid receptor (GR) in visceral adipocytes, a lively expression of LPL by transcription of the LPL gene and posttranslational stabilization of the enzyme. Cortisol and insulin exert powerful effects to both promote lipid accumulation in adipocytes and diminish lipid mobilization in

general. This is most pronounced in visceral adipocytes due to the higher density of GRs.

In concert with growth hormone, sex steroid hormones have opposite effects. Testosterone in the presence of growth hormone affects the stimulation of lipid mobilization, exaggerated by the effect of testosterone to upregulate its own receptor density. This is accomplished by transcriptional effects at several levels of the lipolytic cascade of events, including the density of β -adrenoceptors, cyclase, and hormone-sensitive lipase. Simultaneously, the LPL activity is inhibited. Estrogen has also been found to inhibit LPL.

Visceral Obesity

As mentioned above, several of the hormones of the endocrine system are involved in controlling the rate and direction of fat metabolism. While cortisol and insulin promotes accumulation of visceral fat, growth hormone and sex steroids, often in concert, result in the opposite. Cortisol also exerts chronic effects on lipid metabolism. One of the most striking in humans is the centralization of body fat seen in Cushing's syndrome, exhibited as severe truncal obesity. After successful therapy, the somatic features of Cushing's syndrome disappear.

Mechanisms of Waist-Hip Ratio as a Risk Factor

Visceral fat seems to be metabolically unique compared with subcutaneous abdominal fat. Dr Björntorp suggested that visceral fat results in hepatic insulin resistance via a portal effect of free fatty acids released by increased omental fat. The increased flux of free fatty acids to the liver leads to increased hepatic glucose production and decreased hepatic insulin clearance, which in turn leads to powerful risk factors for diabetes, cardiovascular disease, and stroke. The visceral accumulation of depot fat, as indicated by the simple WHR index, is thus an easily visible and measurable consequence of a profound, multiple endocrine perturbation.

Waist-Hip Ratio as a Sign of Stress

There can be little doubt that chronically elevated cortisol levels can redistribute body fat, as clearly seen in Cushing's syndrome. Excessive and protracted cortisol secretion is the result of a frequently evoked HPA axis, either by environmental or intrinsic factors. Environmental factors include psychosocial and socioeconomic handicaps, alcohol, and tobacco, as well as traits of psychiatric symptoms of depression and anxiety. Such stressors are all known to activate the HPA axis. In primates other than humans,

exposure to stress is followed by a diminished feedback regulation of the cortisol secretion as well as visceral obesity and associated metabolic complications. The WHR may therefore be regarded as a simple anthropometric measurement of frequently repeated or chronic exposure to various forms of stress.

Glossary

Posttraumatic stress disorder (PTSD)

PTSD is a psychological disorder affecting individuals who have experienced or witnessed profoundly traumatic events, such as torture, murder, rape, or wartime combat, characterized by recurrent flashbacks of the traumatic event, nightmares, irritability, anxiety, fatigue, forgetfulness, and social withdrawal.

War is the multifaceted threat to human existence. It exposes people to the health-damaging psychological, physical, chemical, biological, and mechanical stressors. The war has a deep and devastating social and economic impact on the population involved, thus producing additional and lasting repression. It is too soon to make long-term estimates of the damages caused by war in the area of former Yugoslavia, but the data concerning increased social and health

impairments due to the war in Croatia are indicative for the whole area and show the level and the type of vulnerability when humans are exposed to the stress of war. War integrates the deprivation of basic existential needs and of all human rights and values; it eliminates emotional comfort; it causes irreversible material and kin losses, physical exhaustion, and psychological breakdowns; and it makes futile all everyday routines. The first and the only benign response to stress is the escape, but there is no possibility of running away from stress experiences in war – one stressor can only be substituted by another. This is why the full display of adaptation mechanisms takes place in subjects experiencing war stress: changes in behavior, hormonal impairments, neurological disorders, metabolic changes, genetic shifts, and all kinds of diseases. Stress-induced consequences, depending on the severity and the duration of the exposure to the stress experience, can be identified as PTSD, interrupted pregnancies, susceptibility to malignant diseases, cardiovascular insults, suppressed immune response, hormonal disorders, and all types of emotional instabilities or psychological impairments including suicide, homicide, and other types of violence.

Historical and Political Background of the Conflict

The federal republics of prewar Yugoslavia had national and cultural identities with distinct historical backgrounds. At times in the past they were sovereign states, and they have been trying to reestablish their independence ever since they lost it. Neither the first (monarchist) nor the second (communist) Yugoslavia was an expression of the people's will. When the

Berlin wall collapsed, the Soviet block was dismantled, the Soviet Union disintegrated, and the ruling communist party was defeated. The sweeping changes in eastern Europe provided an opportunity for the national republics constituting Yugoslavia to secede freely, as the Czech and Slovak republics have done. In response, the Yugoslav army under the command of the Serbian generals tried to annul the free and democratic decision by the electorate in four of the six Yugoslav republics to separate from Yugoslavia. The Serbs, inspired by the idea of Greater Serbia, were the only nation to support the continuation of Yugoslavia. The Serbian idea of turning Yugoslavia into a greater Serbia triggered the outburst of the latent but strong mistrust and intolerance between the Serbs, on one side, and all other nations, on the other. The Communist Party of Serbia, subsequently re-formed as the Socialist party, had control over the powerful Yugoslav army and turned into an aggressive Greater Serbian force that started to conquer and ethnically cleanse as much as possible of the territory of the republics whose majority of the population had voted for independence. The local people, if not ethnic Serbs, had to leave the occupied territories. Deprived of all goods and rights, they experienced the misery of homeless and jobless refugees. Those who tried to defend their homes were either massacred and killed or put into concentration camps, tortured, and raped. The process started in Croatia in 1991 and ended by North Atlantic Treaty Organization (NATO) intervention in Kosovo in 1999. Instead of democratization and prosperity, first the Croats, then the Bosnians, and at the end the Albanians experienced war, violence, fear, exile, and loss of kin. Macedonia and Montenegro experienced the menace of social and economic turbulence introduced by the hundreds of thousands of refugees that poured into their countries. Only the Slovenians succeeded in withstanding the austerities of Serbian aggression. At least 2.5 million victims (including almost the total population of Kosovo) were expelled from their homes and were, for varying periods, in exile or temporary housing.

Migrations, Ethnic Cleansing, and Social Impact

The first victims of the Serbian aggression were the Croats, who were removed from 30% of Croatian territory. That territory was not only occupied by the Yugoslav army and the local Serbs and ethnically cleansed of Croats; in addition, Serbs from other parts of Croatia or Bosnia were persuaded to resettle in abandoned Croatian homes in the territory cleansed for Greater Serbia. Such behavior escalated

national animosities as the aggression spread further and further. In Bosnia and Herzegovina, 70% of the territory was ethnically cleansed of Croats and Bosnians, and only the Dayton Agreement and NATO intervention stopped the war in Bosnia and forced the Serbs to restrict their control to the Serbian Republic (Republika Srpska), encompassing 49% of Bosnian territory.

In 1991, Bosnia had 4 364 600 inhabitants; 250 000 men were killed during the war and 35 000 women were raped. At the peak of the war, almost 2 million people were displaced. Even a decade after the end of the war in Bosnia, several hundred thousand people still had not returned to their homes.

The total population of Croatia (in 1991) was 4 760 000. It is estimated that 260 000 people left the country during the war. The war in Croatia killed 14 000 people, among whom 43.4% were civilians and 213 were children; 34 000 veterans, 9890 adult civilians, and 1142 children were injured; 7551 people were detainees of concentration camps and 23 000 children lost one or both parents. In addition, 389 433 civilians were displaced within the country (it is estimated that this number is 6% larger because of unregistered people). More than 100 000 houses were destroyed. Hospitals, schools, and many plants and farms were demolished, drastically raising the unemployed and retired percentages of the population and putting exhausting pressure on the remaining working population. There were 870 000 retired people, 260 000 jobless, and only 970 000 employed (compared to 1 650 000 employed before the war). The collapse of order and the rise of poverty, insecurity, and hopelessness were widely reported throughout the population.

Effects on Health

One of the major problems in the interpreting of the effects of war on the health of the population is the great extent of migration associated with the war. Croatia is the only country in the region where health parameters can be followed before, during, and after the war. Although migrations from Croatia and within Croatia were large, the number of displaced people never exceeded 12% of the total population and all the victims of migrations within Croatia are included in the official statistics.

The statistical parameters depict a very gruesome picture of the effects of war on the health of the population in Croatia. The rates of several diseases that are known to be associated with stress, such as diabetes, tumors, cardiovascular diseases, and gastric ulcers, increased sharply during and immediately after the war (Figures 1–2). Infectious diseases also increased

Figure 1 Number of cases of various disease groups registered in general hospitals in Croatia, 1990–1994. Data from Croatian Health Service Yearbook 1997, Zagreb, 1998.

Figure 2 Number of cases of specific diseases registered in general hospitals in Croatia, 1990–1994. Only diseases with the highest increase of incidence are presented. Data from Croatian Health Service Yearbook 1997, Zagreb, 1998.

significantly, probably due to the stress-induced depression of the immune system. Most other diseases displayed a slight decrease in 1991–1992 (mirroring the temporary population decrease at the peak of the war in Croatia) and subsequently returned to the prewar values. The exception is rheumatoid arthritis, which stayed significantly decreased for several years and then increased rapidly to over 150% of prewar values. During this time, infant mortality continually declined,

indicating that there was no significant decrease in the general quality of the health-care system. Despite the preserved level of health care, the postwar health of the population significantly deteriorated due to stress and other effects of war compared to 1990. In 1994, Croatia had 60 000 more cases of infective diseases, 40 000 more people with diabetes mellitus, 32 000 more people with various neoplastic diseases, 30 000 more patients with heart diseases, 40 000 more people

with kidney diseases, and 24 000 additional patients with duodenal or gastric ulcers. Because the total population of Croatia was approximately 4.5 million, the addition of 200 000 ill people represented a substantial burden for an already overloaded health system.

Stress due to the war had a particularly strong impact on pregnancy and prenatal development. In addition to a decreased birthrate, as is usual in the time of hardship, there was a continuous increase in extrauterine pregnancies and other complications during pregnancy and delivery. In addition and completely unexpected, there was a sharp increase in various inborn defects (Figure 2).

Effects on Mortality

In addition to the decreased birthrate, the war diminished the population by increasing the mortality (Figure 3). Not taking into account the 14 000 people killed during the war, the most prominent immediate effect of war on the Croatian territory was the more than doubling of the rate of mortality from ischemic heart diseases, resulting in the unexpected deaths of more than 6000 people during the two war years 1991 and 1992. The prolonged effects of war, manifested in a ruined economy and prewar social structures, still kills people with an annual rate of approximately 4000. The increase in the ischemic heart disease alone has taken more human lives than were killed during the whole war in Croatia. Unfortunately, due to the massive migrations in Bosnia and Kosovo, it is not possible to determine the exact numbers for them, but if the percentage of people killed was similar to that in Croatia, several hundred thousands people probably died because of stress.

It is worth noting that, in addition to the stress imposed by the war, the transition from a centralized socialistic economy to a free-market economy

introduced stressful existential problems to a part of the population, which probably also contributed to the increased mortality from ischemic heart disease. One recent study in Lithuania reported that the break-up of the Soviet Union resulted in a quadruple increase in the mortality rate from ischemic heart diseases for some age groups. However, in other countries, such as Hungary and Poland, this pattern is not so prominent. The transition in Croatia is expected to be less stressful than in other socialist countries because even during socialism Croatia was open to the West and had accepted a few elements of the market economy. Thus, the war and its consequences remain the major factors influencing the increased mortality from ischemic heart disease in Croatia.

Effects on Social Behavior and Violence

Quantitative analysis of the psychological effects of war on the Croatian population is limited to the subjects who were/are seeking medical help. However, only a small number of individuals suffering from psychological disorders are under medical surveillance. There are more than 10 500 diagnosed cases of PTSD; many more are unregistered. Studies estimated that patients suffering from PTSD have up to a sevenfold increased incidence of suicides and fourfold increased risk of death from all external sources. Violence in general has increased, but it is very hard to know the exact figures because the health-monitoring statistics do not include violent behavior in their reports and official policy makers in Croatia refuse to acknowledge the incidence of violence and suicides to be disturbing. However, some trends are clearly visible. During and immediately after the war (1991–1992), there was a twofold increase in the level of violence, both as reported in police statistics and in hospital admissions. Although, according to

Figure 3 Number of live births and deaths per 1000 people, 1990–1997. Data from Statistical Yearbook 1998, Republic of Croatia Central Bureau of Statistics, 1998.

Figure 4 Number of suicides and attempted suicides in different age groups in Croatia, 1990–1998. Data from official statistics of the Ministry of Interior of the Republic of Croatia.

the same sources, the reported homicides and violent crime returned to prewar values in subsequent years, there is a disquieting increase in suicides and other self-inflicted injuries in young people. The number of young people committing suicide is continuously rising, and compared to 1990, in 1997 this rate is doubled or quadrupled, depending on the age group (Figure 4). In the last four years, primary and secondary schools report a rapidly growing number of hyperactive and aggressive children who need special care in the classroom. The incidence of depressive symptoms and insomnia is reported to be great in the elderly and in veterans. Drug abuse is disturbingly frequent compared to the prewar statistics, but the number of treated addicts has remained constant. It is correct to attribute these changes in behavior to the stress imposed by the war, and it is interesting how the various target groups (children, the elderly, veterans, etc.) within the population have responded differently to the stress.

Conclusion

The majority of the population in each of the states originating from the former Yugoslavia has experienced war stress. Various health and social disorders evolved from that experience. Although the data presenting the consequences of the war stress are incomplete and although they are, because of the availability, reduced to Croatia only, they provide unique evidence of human vulnerability when living through war.

Stress Management in War

Glossary

<i>Intifada</i>	Palestinian uprising against the occupying forces.
<i>Nakbeh</i>	The disaster (Arabic).
<i>Sacrifice</i>	The slaughter of an animal or a person or the surrender of a possession as offering to a deity, made holy by religious association.
<i>Suicide</i>	The act of a person intentionally killing him- or herself.
<i>War</i>	A quarrel between nations conducted by force, a state of open hostility.

Background

It is the hope of the author to present, from a clinical perspective, the experience of war, suicide, and sacrifice. For centuries, people have launched wars with other nations and peoples to pursue ideals, goals, or possessions. Others have fought wars in self-defense and in anticipated concern about their safety. Others have been invaded and occupied and have resisted the occupation through warlike tactics. People have committed suicide, for a purpose or for no purpose, because of an ideal or an illness. People have sacrificed so that others can benefit; this altruism has been a characteristic that elevates humans from the selfish and decadent position that they can become fixated on.

In the Middle East, the Palestinian-Israeli conflict goes back several decades, and it is impossible to address all the issues here. However, a summarized orientation to the problem is necessary to understand the trauma and stress sustained by this population. The following years are significant:

- 1948 – The Nakbeh (the disaster, in Arabic) is the word used by the Palestinian population to refer to

the partitioning of Palestine and the massive Palestinian refugee exodus and displacement. The Israelis refer to this same period as their independence day.

- 1967 – The 7-Day War and the occupation of the rest of Palestine by the Israeli armed forces.
- 1989 – The first Intifada, the Palestinian people's uprising against the occupying forces.
- 1994 – After the Oslo talks, the declaration of the Palestinian Authority.
- 2000 – The second Intifada, a rekindling of the first Intifada after major disappointments and tragedies that continued in the area despite the Palestinian Authority's presence.
- 2004 – The building of the separation wall, still in progress in 2006.

Theory

The psychoanalytic model is a scientific perspective that has been used by the author in her 25 years of clinical experience as a psychiatrist dealing with traumatized patients. The author's clinical experience has allowed her the opportunity to compare cases from economically impoverished areas such as the ghetto of Los Angeles and the refugee camps in Palestine, along with more economically viable areas such as Hollywood and Jerusalem. War here is considered to be a state of open hostility possibly causing trauma to individuals and the masses alike. The individual or national reaction to such hostility remains a very personal experience, even from a national perspective. Some people are traumatized from such hostility; others are rendered stronger and more resilient, determined, and creative. Both the aggressors and those experiencing aggression should reflect on this and perhaps learn to refrain from aggressive behavior; aggressors give those experiencing aggression a chance to become noble and most creative, resilient, and determined, and if those experiencing aggression become aggressive in return they lose their values and become the same as the original aggressors.

Trauma is an experience that can be caused from within or from the outside. That means that people can experience trauma internally without anyone contributing to this phenomena. This situation of internal conflict is well known to psychiatrists, who are constantly challenged with such circumstances. External traumatizing events and their impact on people's psychological well-being have been very clearly and concisely defined and presented in the diagnostic criteria for posttraumatic stress disorder

(PTSD) in the *Diagnostic and Statistical Manual of Mental Disorders* (4th edn.; DSM-IV) and subsequent articles on the subject.

The Middle East conflict seems to tie together many important aspects of our civilization: politics and the search for democracy; religion or the lack of it, and its abuse through fanaticism; justice and its continued absence, leading to intolerable injustice; violence and aggression; gender difference; equality and the lack of it; pride and the feeling of superiority and being chosen, leading to prejudice and the dehumanizing of the other; occupation that is viewed as liberation for others; terrorizing others and the feeling of being terrorized at the same time; and war and the yearning for peace. Here I present a psychoanalytic look at the Middle East conflict, hoping that it sheds light on the 50-year conflict and encourages the different parties to engage in deep reflection, seeking the answers in an arena that has not been explored before. I believe that human nature and people's unconscious processes and defenses are interfering with the capacity of the people involved to seek and realize peace, whereas a scientific understanding of these processes might alter the escalating cycles of violence and convince people to adopt a different approach, one that will lead to a lasting peace. This then could serve as a model for other areas of escalating conflict and confrontation.

Let us first examine the basic ideas behind the understanding that led to the conclusions presented here. The work of Sigmund Freud was at the basis of the understanding that was later developed by Melanie Klein that the power of the unconscious and its impact on human existence needs to be addressed. To become conscious of unconscious processes liberates people, who can then either choose to be led by their neurotic thoughts or choose to venture into a life of free choice, risk taking, and responsible action led by thought and reflection rather than by impulse and magical thinking. Freud taught us about the defense mechanisms in the human mind and attitudes, namely the early defenses of splitting and projecting. As evidenced in many human relationships, and certainly in politics, the good and the bad reflect this very notion of splitting, seeing the self as good and the other as the enemy on whom all kinds of evil projections can be accommodated. Melanie Klein further developed these thoughts with the idea of projective identification. She suggested that when magical thinking is used to develop a person's wishful thoughts (in action or in thought) it renders the person responsible for the possible damage that occurs to other people, regardless of the real cause of this damage. The sense of responsibility or guilt may lead to self-punitive behavior or feelings, but it is the feeling

of entrapment that can cause more damage, tarnishing the person's life; that is, the person may feel that, if he or she magically caused irreversible damage in other people's lives, then this magical fate is the only possible fate.

Clinical Research

The work presented here is based on many years of clinical observations.

- 1984 – The author observed and analyzed the drawings of 50 children in three refugee camps in Palestine. The drawings were compared to those of children in the same age group in the Los Angeles County Hospital's children's inpatient unit. The drawings of the children living in the Palestinian refugee camps were more often about healthy community activities scenes such as picking olives in the fields, weddings, and home scenes; the inpatient children's drawings in Los Angeles were more morbid, showing bars, blood, and death scenes and issues.

- 1991–1994 – As mental health supervisor for the United Nations Relief and Works Agency (UNRWA), the author gathered clinical evaluations. The reports indicated that, of 1500 new cases seen yearly, 450 children were diagnosed as having pervasive developmental disorder, 350 as having depression, and approximately 250 as having PTSD.

- 1992 – During the first Intifada, the author visited the same three refugee camps as in the 1984 study and examined the drawings of 50 children in each camp. These drawings had an extremely different tone; they were overwhelming in their gory depictions of pain, blood, barbed wire, prison and death, violence, and injustice.

- 1996 – Mental health workers, social workers, and psychologists randomly administered 360 questionnaires in the West Bank. These questionnaires were translations from English of DSM-IV criteria. The diagnostic criteria for three disorders was analyzed and used: PTSD, depression, and pervasive developmental disorder. The results indicated an alarming 35%, 40%, and 45% incidence, respectively. These results will be reassessed soon to evaluate the impact of the second Intifada and the continued unrelenting trauma that has haunted the area.

Clinical Experience

It has been the experience of the author that, although war is traumatizing, it does not necessarily have a paralyzing effect on the population. Aside from the obvious trauma of the loss of people's lives and property, heritage and development, health and hope, it is the observation of the author after 20 years of living

among and serving this population that the reality of becoming refugees, being displaced, losing loved ones, and tolerating a great deal of frustration and humiliation has not turned the masses into desperate people who let their impulses and instincts control them; instead, people who recognize the wisdom of maintaining educational pursuits and developing future generations who will honor their traditions seem to be the norm. The fact that some people resort to the idealization of martyrdom, death, and violent suicide/homicide remains to be understood and investigated. Next I present the results of my clinical experience and research done to try to analyze and understand this phenomena.

As part of the initial assessment of the children at the Guidance and Training Center for the Child and Family (GTC) in Bethlehem, the author asks the children to express three wishes. In the mid-1980s, the children expressed many very creative wishes expressing a great many ambitions and objectives in life. In the mid-1990s, 10 years later, the majority of the children did not express any wishes; they remained silent. After some psychotherapeutic intervention, if they expressed any wishes, the wishes all could be summarized as a wish to become a *shaheed*, a martyr. This inability to express wishes followed by a wish to become a martyr indicates a paralysis of the mind and creativity and a total embracing of a death wish. These children can relinquish these thoughts after a solid psychotherapeutic intervention and a facilitation of their reintegration into the school system.

Clinical Vignettes

Patient 1 A young woman, a would-be suicide bomber, spoke on local public TV about her previous intentions to blow herself up for what she thought was a nationalistic pursuit and about how, feeling uncomfortable with her plans, she sought psychotherapy. Then, she spoke about her change of heart after her psychotherapeutic experience at our center. However, she reported that she had been unable to convince her brother to come in for treatment and that he ended up as a suicide bomber, killing himself and others.

Patient 2 Another patient, a 7-year-old boy, was brought in for treatment because he was sleepwalking at night; this behavior endangered his life, especially because the city was under curfew during most of the period when the child exhibited this behavior. It turned out that this child had been arrested and taken for interrogation for throwing stones at the occupying forces. During the arrest, his grandmother tried to stop the soldiers from taking the child; she was pushed and she fell, hurting her head and landing

in a pool of blood. The boy thought she was dead as he was taken for his interrogation. But on his release a few hours later, he saw that his grandmother was well and not dead as he had feared. Following this episode, the child started to exhibit a phobia about leaving the home and refused to go to school; he eventually presented with sleepwalking, which led to his being brought in for treatment.

During his therapy, when the boy was asked about dreams, he reported having a repetitive dream of someone kidnapping him and putting him in dangerous situations. When the author said that she might know who the kidnapper was, the child was surprised and interested in the answer. The author told him that she thought he was both the kidnapper and the kidnapped because he was the author of the dream and therefore was trying to tell us something about himself – that he kidnapped himself at night while asleep and put himself in dangerous situations. The dream also was residual trauma from the arrest and interrogation that he sustained, but it was interpreted at a deeper level because the child was receptive to this level of interpretation, and he eventually benefited from the interpretation. The sleepwalking stopped, and the child was able to go to school and did not continue to repeat the trauma that he had sustained by having this disturbing dream and exhibiting dangerous behavior that could have cost him his life. The child felt guilty about his grandmother's injury and felt he had caused it by his behavior, which led to the army's intrusion into their home. He felt identified with this projection and trauma and wanted to feel in control through this repetitive dream of the kidnapper. He felt guilty and entrapped by the fate that he thought he caused his grandmother to have.

Patient 3 Another patient, a breast-feeding mother, told the author, "This infant I can feed this way, but the others at home, how will I feed them? If someone were to give me a bomb, I would go to the checkpoint and blow myself up. This way, my children at least will be proud of their mother, the martyr." The author took this into consideration as she continued to treat this patient and offered her an income-generating opportunity at the clinic doing some embroidery. This woman is now taking care of her family and running an income-generating embroidery project of her own, helping other women sustain their livelihoods and those of their families.

Research

A brief study was carried out at the center to assess the impact of the separating wall being built by the Israeli government on the population living in the West Bank,

asking people's views of this new cement barrier separating them from the families that had been living next door to them prior to this construction. The study also assessed people's views vis-à-vis the Holocaust.

The questionnaire was given to 30 Palestinian professionals; the results are shown in Table 1. Twenty years ago, the results for the last four questions were as listed in Table 2. When the present-day results are compared to the assessments made 20 years ago, it becomes apparent that this construction has decreased

Table 1 Assessment of the views of Palestinian professionals vis-à-vis the Holocaust and the separation wall being built by the Israeli government^a

Question	Yes	No
1. Wall will destroy life in Palestine	28	2
2. Wall will help Palestinians get a Palestinian State	7	23
3. Wall will eliminate Palestinians by Israel	25	5
4. Israelis are doing to Palestinians what Hitler did to them	23	7
5. Consider Jews living through a massacre in Germany	28	2
6. Feel sad about Holocaust	22	8
7. Feel happy about the Holocaust	1	29

^aN = 30, 20 males and 10 females.

Table 2 Assessment of the views of Palestinian professionals (questions 4–7) 20 years ago^a

Question	Yes	No
4. Israelis are doing to Palestinians what Hitler did to them	20	10
5. Consider Jews living through a massacre in Germany	29	1
6. Feel sad about Holocaust	29	1
7. Feel happy about the Holocaust	1	29

^aN = 30.

the compassion people feel toward the other side and increased their feelings of being oppressed and persecuted.

After the construction of the separating wall and the population's increasing feelings of frustration and desperation, and the claim by the other side that the construction of the separating wall would provide security for the Israelis, the author investigated the opinion of the community about suicide bombers. The idea for this questionnaire came from the observation, first with children and then with adults, that those who came to the center for psychiatric and psychological treatment expressed wishes or plans to become suicide bombers. After these patients received psychological interventions at the center, which either facilitated their being mainstreamed back into the school system or into the workforce, these thoughts of suicidal/homicidal plans disappeared and were replaced with hope and gratitude toward the people who helped them find hope for the present and future; they relinquished their death wish and embraced a life wish.

The questionnaire was given to 91 mental health workers; the results are shown in Table 3. They indicate that a high percentage of the population honor and glorify this sacrifice and do not view it as reflection of emotional difficulties, seeing suicide bombing as the patriotic sacrifice of a hero, done in the name of God, and not as an expression of suicidal thoughts, depression, or psychological injury. The results show that suicide bombers are seen as desiring revenge, being aware of what they are doing, and not feeling guilty about the pain of other people. These ideas are not the same as those expressed by the population that comes for consultations at the guidance and training center, as presented in the earlier material.

Further research is planned that may help us further understand the state of mind of the populations in this area. This includes a study comparing trauma

Table 3 Assessment of views about martyrdom (%)^a

Do you think that the people who conduct martyrdom operations:	Yes	No	No answer
1. Desire to commit suicide?	17.6	76.9	5.5
2. Do a patriotic sacrifice?	84.6	12.1	3.3
3. Do a sacrifice in the name of God?	83.5	13.2	3.3
4. Do it due to their difficulties in life?	60.4	35.2	4.4
5. Suffer from depression?	49.5	44.0	6.6
6. Are psychologically hurt?	64.8	28.6	6.6
7. Desire revenge?	84.6	9.9	5.5
8. Are aware of what they are going to do?	45.1	49.5	5.5
9. Feel guilty about the pains of other people?	34.1	60.4	5.5
10. Are heroes?	46.2	49.5	4.4

in Palestinian and Israeli populations and the capacity to forgive and a study comparing the mental health disorders observed in Palestinians living in West Bank to disorders in Palestinians living in Lebanon.

Stress Management in War

Although it is well known that suicide attempts, psychotic episodes, and admissions to psychiatric hospitals increase after a war is over and there is peace, it is the author's observation that the mental health demands in Palestine are increasing and becoming overwhelming. It is with this in mind that the interventions discussed here are being provided. The prediction that things will become even worse when there is peace in this area makes the author concerned about meeting these increasing mental health needs, and the author hopes that the prediction is wrong. The mental health services are not sufficient at the present time, and should things continue to deteriorate, the outcome is of concern to many health workers.

The use of psychoanalytic interventions and understanding, behavioral and relaxation techniques, special education therapy, individual (talk or play) and group therapy, medications, and other modalities to reduce stress and trauma in the population has become common. A thorough initial evaluation and treatment plan are necessary for each patient who consults a treatment center, and the provision of mental health services is urgent and necessary at this time.

That a majority of the population does not pursue psychotherapeutic assistance and yet seems to manage and maintain its existence and sanity implies that human nature is capable of self-healing and reasoning, of developing the necessary wisdom through people's own thinking and their culture and religion to pursue healthy avenues in their decision making, taming their aggressive impulses and discovering on their own that in this way creativity is allowed to develop and flourish. The few individuals pursuing violent resistance seem to hurt the cause and the people themselves more than help them. This leaves the author concerned about the repercussions of such attitudes; two wrongs never made a right. This is explained by Klein's projective identification defense, as previously elaborated on. The fact that war has contributed to the confusion of suicide with sacrifice should not cause mental health workers to confuse the issues; they should always try to sort things out in a clear and ethical way, trying to provide patients with inner harmony, helping them think more clearly and wisely through the psychotherapeutic intervention.

It is important to also mention that in times of war and political chaos and injustice it is the moral obligation of the mental health workers to maintain a standard of ethical service to the community and to try to attend to the needs of the masses by training others who can provide triage and quality interventions and by using the media (magazines, newspapers, radio, and television) to present mental health issues and prevention-measures training. All these different interventions have proved to be worthwhile efforts during the author's years of experience in the Middle East. Along with attending to the needs of the masses from a mental health perspective, it is also important to keep in mind that help along the lines of mainstreaming kids back into the school system is essential and that providing income-generating projects for the population may play a role in preventing disasters.

Working in a vacuum is not a creative way to intervene, and the involvement of professionals who are eclectic, versatile, creative, and passionate about their work makes the difference between touching people and helping them versus observing, reporting, and being afraid to get involved in the struggle to find and spread inner harmony.

<i>In vivo exposure</i>	Exposure to a real-life situation.
<i>Pharmacological</i>	Having to do with drugs.
<i>Psychometric</i>	Quantitative assessment of psychological trends and measures.

Introduction

Some service members handle their transition from the war zone to the home front in a matter of weeks. Others require more time, and perhaps assistance. A significant minority fall short and develop posttraumatic stress disorder (PTSD), depression, alcoholism, some other psychiatric problem, or functional impairment. Although the present focus is PTSD, these other potential postdeployment problems should not be overlooked. The treatment of PTSD in veterans is similar in many ways to the treatment of PTSD in the civilian population, with some special considerations. Although there are universal aspects to any combat experience, every war is different, thereby posing unique challenges to the practitioner. For example, 50% of American troops that served in Iraq and have left active duty are members of the National Guard or Military Reserve rather than active duty combatants. This has implications for the identification and treatment of PTSD in this cohort.

Stressors

Traditional severe combat stress involves situations in which a service member experiences comrades being killed or injured; having personally killed enemy combatants and, possibly, innocent bystanders; uncontrollable and unpredictable life-threatening attacks; and more. In addition to direct combat stress, a variety of other war zone stressors are experienced, such as feeling helpless to alter the course of potentially lethal events, observing or handling the remains of civilians and soldiers, and observing devastated communities produced by combat. Military sexual trauma (MST) is now known to be highly prevalent, affecting both women and men in combat. An unprecedented number of military personnel are surviving serious injuries due to dramatic advances in medical technology, and being wounded in battle is associated with the highest PTSD rates. This may be compounded by the impact of life-changing severe injuries such as traumatic brain injury (TBI), traumatic amputations, spinal cord injuries, and blindness.

A common denominator for many returnees is the sustained hypervigilance and persistent anxiety about potential threats at any time or place, which often leads to difficulty transitioning from the theater back to civilian life. Clinicians faced with patients who have had a difficult re-entry to the home front need to be aware of this reintegration process. They must consider the likelihood that postdeployment difficulty for a particular patient may be part of an otherwise normal readjustment trajectory or could be manifestations of a clinically significant problem such as PTSD.

Assessment and Diagnosis

A routine assessment should begin with a few questions about the patient's exposure to war zone trauma and other traumatic experiences. Once the presence of traumatic exposure is established, the following step is to screen for PTSD. The National Center for PTSD has developed a four-item (yes/no) screen with excellent psychometric properties (Primary Care PTSD Screen [PC-PTSD]).

Designed for use by primary care practitioners, the PC-PTSD consists of four questions, one from each PTSD symptom cluster, asked in reference to the past month: (1) Have you had nightmares or thought about the trauma when you did not wish to? (re-experiencing), (2) Have you tried to avoid thoughts and situations that remind you about the event? (avoidance), (3) Are you easily startled or frequently on guard? (hyperarousal), and (4) Have you felt numb or detached from other people or things? (numbing). A patient that endorses three of the four items should

receive a more thorough assessment for PTSD. Recent research with the PC-PTSD shows that it correctly positively identifies those that have PTSD 78% of the time (sensitivity) and correctly negatively identifies those that do not have PTSD 87% of the time (specificity).

Given sufficient evidence from screening that the patient may have PTSD, a more formal assessment is warranted. This can be accomplished through a comprehensive diagnostic interview in which each of the 17 PTSD symptoms is assessed, by use of a structured clinical interview such as the Clinician Administered PTSD Scale (CAPS) or using well-validated self-report questionnaires such as the PTSD Checklist (PCL), the PTSD Diagnostic Scale (PDS), the Davidson Self-Rating PTSD Scale, or others.

There are a few things that clinicians need to keep in mind when dealing with veteran patients. Clinicians should be aware that service members often fear being stigmatized if they disclose any sign of psychiatric problem, including PTSD. Furthermore, those that are most symptomatic are more likely to feel stigmatized and therefore less likely to seek treatment. It is also necessary to recognize that although social support is a powerful protective factor against developing PTSD, it is much less available to National Guard and military reservists and their families than to full-time military members. Whereas the latter may inhabit military bases where many military families live close together, undergoing the same deployment stressors, reservists, and especially their families, are neither embedded in a full-time military culture nor surrounded by others who share their plight. This may explain why reserve troops in the Persian Gulf War had higher prevalence of PTSD and depression than active duty personnel.

Treatments

Effective evidence-based psychotherapeutic and pharmacological treatments for PTSD are available. Detailed discussion of the empirical treatment literature can be found in clinical practice guidelines.

Psychotherapeutic Treatments

Clinical guidelines published to date designate cognitive-behavioral therapy (CBT), which includes cognitive therapy, prolonged exposure, and cognitive processing therapy, as the treatment of choice for PTSD. CBT techniques are designed to alter the conditioned fear and cognitive distortions associated with PTSD. Prolonged exposure essentially involves clinicians asking patients to construct narratives about intolerable traumatic events they can recall.

With repeated, therapist-guided exposure to these traumatic memories (imaginal or *in vivo*), patients experience progressive reduction in distress and thereby achieve clinical remission. Cognitive therapy and cognitive processing therapy focus on changing the maladaptive automatic thoughts associated with PTSD. Cognitive restructuring is a technique through which the therapist challenges distorted beliefs (perceiving the world as dangerous, seeing oneself as powerless or inadequate, or feeling guilty for outcomes that were outside of one's control), thereby enabling patients to overcome intolerable trauma-related emotions. Exposure and cognitive therapies have performed very well and with equal efficacy.

Eye movement desensitization and reprocessing (EMDR) is a technique that involves patients being instructed to imagine a painful traumatic memory and associated negative cognitions while visually focusing on the rapid movement of the clinician's finger. Although there are now many studies showing that such eye movements are not needed for EMDR to work, evidence-based practice guidelines indicate that EMDR is an effective treatment despite the lack of a defined mechanism of action.

In practice, both exposure and cognitive therapies are considered first-line treatments for PTSD. In exposure therapy, a clear memory of the traumatic event must be accessible. For cognitive therapy, the focus is primarily on the automatic, erroneous cognitions and behaviors that are associated with traumatic memories. In practice, exposure therapy has successfully addressed erroneous cognitions, and cognitive therapy has successfully addressed fear-based avoidant behavior. Therefore, at this time, the choice of CBT therapy for PTSD is up to the clinician. Given the scarcity of trained CBT therapists, neither option of evidence-based treatment may be available.

Pharmacological Treatments

A number of medications have been tested as treatment for PTSD patients. Selective serotonin reuptake inhibitors (SSRIs) are currently the treatment of choice, and the U.S. Food and Drug Administration has approved two, sertraline and paroxetine, for the treatment of PTSD. What has been especially exciting about the SSRI results is that these drugs appear to be broad spectrum agents that work to reduce all the symptom clusters of PTSD. Successful randomized clinical trials have also been conducted with the SSRI fluoxetine, the alpha-1 adrenergic antagonist, prazosin, tricyclic antidepressants, monoamine oxidase inhibitors, and venlafaxine. Because the psychobiology of PTSD is complex, other medications such as antiadrenergic agents, anticonvulsants, and a

variety of agents currently under investigation may prove as effective as SSRIs. Finally, randomized trials of benzodiazepines have yielded negative results, so this class of medication cannot be recommended for PTSD treatment. When choosing medications and other elements of treatment, keep in mind that PTSD is highly comorbid with other psychiatric problems.

Summary

Many important questions about treatment have yet to be tested systematically. These include how to select treatment, define realistic goals, combine various treatments, and approach complex comorbid conditions; how long to stick with a specific treatment; and when to acknowledge clinical failure. As new psychotherapeutic and pharmacological treatments are developed and empirically tested, these essential questions should also be addressed. In the meantime, it is essential that clinicians select evidence-based treatments whenever possible.

Gaps and Needed Research

Glossary

Family

Responsibilities and activities that arise from shared goals, values, and long-term commitments among two or more people who are related by common ancestry, adoption, marriage, and other legal or socially recognized unions.

Work

Responsibilities and activities inherent in an individual's trade, profession, vocation, or other means of livelihood.

Work-family conflict

The extent to which an individual's work interferes with his or her family or an individual's family interferes with his or her work.

<i>Work-family facilitation</i>	The extent to which an individual's work benefits his or her family or an individual's family benefits his or her work.
<i>Work-family interface</i>	Areas of physical, psychological, social, or temporal overlap in which an individual's work and family affect each other.

Defining Work-Family Balance

Work-family balance remains largely undefined despite its frequent use in both the popular and scholarly vernacular. One influential definition characterizes work-family balance in terms of equal engagement in both work and family responsibilities. This definition of work-family balance is influential because it is clearly grounded in theory and is consistent with the balance metaphor. Despite these strengths, however, the definition overlooks several important complexities such as the multiple forms or ways in which individuals can engage in their work and family lives, and whether or not different forms of engagement are functionally equivalent. Recognizing these complexities, more recent definitions of work-family balance continue to highlight notions of equality, but they also emphasize comparable levels of satisfaction within each domain and the relative absence of conflict between the domains. Work-family balance, therefore, generally refers to a work and family life that is well integrated and a situation in which the individual is actively engaged in both domains.

Prevalence and Emergence of Interest in Work-Family Balance

Difficulty maintaining work-family balance is reported by the majority of working adults. Estimates from the U.S. General Social Survey suggest that fewer than 40% of adults believe that they are successfully balancing their work and family lives. The widespread difficulty in achieving work-family balance, and subsequent scholarly and popular interest, results from significant socioeconomic shifts in the constitution of the labor force as well as in the nature of work itself. In the final quarter of the twentieth century, women's labor force participation increased dramatically, particularly among women with children. The proportion of children being raised in a single-parent household increased, as did the rate of employment among single parents. Concomitantly, substantial job growth in the service-producing sector coupled with increased global competition created new demands on the labor force, such as increased use of contingent labor and other flexible staffing models, as well as greater need for work that occurs outside the bounds of traditional business hours.

The shifts in work and family in the later portion of the twentieth century made navigating daily work and family life more complex for many adults. Growth in women's labor force participation challenged the gender-based division of labor and brought basic issues related to household management and childcare to the forefront. Securing high-quality and affordable childcare is an ongoing challenge, as is care for sick children and elder care. The transition to a service-based economy was accompanied by a fall in real wages, particularly among lower and working-class families. Globalization and the increased reliance on contract and contingent employment arrangements elevated concerns over job insecurity and raised new questions about the nature of the employer-employee relationship. Technology and the 24/7 economy has redefined when, where, and how work is performed for a substantially larger portion of workers. The increased complexity of daily work and family life for many adults has fueled widespread interest in the causes and consequences of work-family balance.

Work-Family Balance and the Stress Process

Work-family balance has been applied and studied at two major points in the stress process. Work-family balance or, more typically, imbalance, is frequently conceptualized as a primary stressor. The basic theoretical rationale for viewing imbalance between work and family as a primary stressor is that the social roles of employee/worker, spouse, and parent have substantial social and cultural value and, therefore, play a central role in adults' identity and sense of self. Indeed, some researchers suggest that successful integration of work and family life is a central task of adult development. If work and family are out of balance, there is substantial social and personal pressure placed on individuals to better manage their responsibilities.

Multiple lines of research support the view of work-family imbalance as a primary stressor. Adults seek to maintain work-family balance through a variety of strategies such as changing jobs, reducing hours, renegotiating household responsibilities, cutting back on personal leisure pursuits, and modifying standards or expectations for their work and family life. Individuals who do not have a well-balanced work and family life – typically operationalized in terms of high levels of work-family conflict – have less life satisfaction as well as elevated levels of depression and somatic complaints, conditions frequently implicated in the stress response. Corroborating this research is more recent evidence linking indicators of work-family balance to common physiological stress responses such as elevated blood pressure, heart rate,

and cortisol. Social support from co-workers, supervisors, or family members has been found to buffer the effects of poor work-family balance on stress-related outcomes such as levels of distress and domains of life satisfaction. In summary, there is a wide evidence base suggesting that work-family balance behaves like a primary stressor.

Other research situates work-family imbalance as a secondary stressor, or a downstream consequence of other circumstances or events. This research exists in two largely separate streams of inquiry. In the first stream, work-family balance is studied as a consequence resulting from the relative availability of work- and family-related resources to meet the demands of work and family life. This research focuses on work-related demands such as the time and timing of when work is performed, features of the work such as the amount of authority and variety workers are given, the availability of family-friendly policies such as flexible work schedules or on-site childcare centers, and the supportiveness of co-workers and supervisors. On the family side, research tends to focus on the number and ages of children, the employment status of adults in the family (e.g., dual-earner versus single-earner), qualities of intrafamily relations such as levels of conflict among partners, and the division of household labor. In the second stream of research, work-family balance is seen as a mechanism through which broader social forces exert influence on individual outcomes. For example, some investigators argue that observed health disparities, particularly in child health and development, result (at least in part) from the social allocation of demands and resources necessary for successfully balancing work and family. Racial and ethnic minorities as well as individuals with a low education, for example, are overrepresented in jobs requiring nonstandard schedules that provide few (if any) formal programs that assist workers in balancing their work and family responsibilities. Despite these arguments and the fact that the current focus on work-family balance is a consequence of profound sociostructural changes in work and family, the literature is dominated by views of balance as a personal challenge confronted by individuals.

Promoting Work-Family Balance

Given the stress-related consequences of work-family imbalance, both individuals and organizations may be motivated to take action to restore or maintain balance. Individuals who set goals and employ adaptive strategies to reach those goals are less likely to experience conflict between work and family. An active coping style and social support are also associated with greater work-family balance. Organizational

interventions to improve balance typically focus on offering family-friendly benefits designed to facilitate management of conflicting role demands. Such benefits are broad and varied, including flexible scheduling, on-site daycare, and eldercare assistance. These benefits tend to be underutilized by workers, and evidence regarding their efficacy for improving balance is equivocal. Family-supportive organizational cultures, of which family-friendly benefits are but one feature, are also widely believed to be essential to promoting work-family balance.

Gaps and Needed Research

Understanding of work-family balance is undermined by several conceptual and methodological gaps in the literature. Conceptually, although most researchers agree that work-family balance represents some vague notion of equality and harmony in an individual's work and family life, it is not clear what work-family balance is or whether the balance metaphor is appropriate. Moreover, there is very little theoretical work underlying work-family balance research. Methodologically, measurement of work-family balance remains encumbered. Most studies rely on single-item measures (e.g., How successful do you feel at balancing your paid work and your family life?). There is currently a division in the literature regarding how to measure work-family balance: some scholars advocate the use of individuals' overall appraisals of balance, whereas others suggest that work-family balance is a latent construct best measured indirectly using indicators of work-family conflict and work-family facilitation. Future research needs to systematically evaluate the strengths and weaknesses of each approach and develop recommendations. Although there are notable exceptions, work-family balance research is also overly reliant on cross-sectional cohort designs, convenience samples, and self-report measures. Research is needed that clarifies the conceptual meaning of work-family balance, develops valid and innovative measures of work-family balance, and studies the phenomenon using multiple methods.

Concluding Remarks

Glossary

<i>Allostatic load</i>	The cost of adaptation (allostasis), reflecting wear and tear on the body systems and processes that increases the risk for disease.
<i>Cardiovascular illness</i>	Circulatory disturbances such as hypertension, myocardial infarction, and stroke.
<i>Demand-control model</i>	Defines work strain as a combination of high workload and low control. The dimension of social support has been added to this model.
<i>Effort-reward imbalance model</i>	Stress and health risks are created by an imbalance between high effort and lack of adequate rewards (money, status, support).
<i>Musculoskeletal disorders</i>	Degenerative processes, damage, inflammation, and pain in muscles and joints in the body (neck, shoulder, arms, lower back, etc.).

Introduction

Work has a very central role in most people's lives. In industrialized countries, there have been quite dramatic changes in the conditions at work during the past decades, caused by economic, social, and technical development. Today, as a consequence, people at work are exposed to high quantitative as well as high qualitative demands and to hard competition, caused by a global economy, multinational companies, lean production, downsizing, and increased demands for efficiency. Fewer employed people are expected to produce more, and experiences of stress due to overstimulation have become a serious problem. At the same time, a considerable part of the population is unemployed or only temporarily employed, because no jobs are available or because they have an inadequate or insufficient education. These people experience stress mainly due to lack of economic resources and understimulation. This polarization of the labor market is likely to have contributed to the social gradient in health and well-being, which has increased in recent years. This article summarizes present knowledge regarding how the modern work environment may contribute to stress and negative health outcomes.

The Role of Work

Most adults spend a large part of their daily life at work. As a consequence, conditions at the workplace

are likely to be of considerable importance for people's mental as well as physical well-being. Work has a central role in people's lives, and a stimulating job may contribute to a more meaningful life, a higher sense of self-esteem, social ties, and economic independence – conditions that characterize positive human health. Work also creates a time structure in daily life and is a major determinant of the individual's socioeconomic status. Negative psychosocial conditions at work, such as a low job satisfaction and lack of influence and control, are known to be associated with various health risks.

Changing Work Conditions

During the past century, the work situation in industrialized countries has undergone profound changes. For women in particular, these changes have been quite dramatic. At the beginning of the twentieth century, women were often involved in heavy physical work (e.g., working in the fields as a farmer's wife). As urbanization increased in the middle of this century, a married woman was generally expected to assume the role of homemaker, with the primary duty of taking care of her children, husband, and home or household. In the last part of this century, an increasing number of women entered the labor market, and in the Scandinavian countries (as well as in many big cities all over the world) the labor force today comprises practically the same number of women as men. However, despite women's greater involvement in paid work and their importance for the family economy, their responsibility for unpaid work at home does not seem to have been reduced accordingly. In keeping with this, employed women often report stress from work overload and role conflicts.

In the modern work environment, physical hazards and demands have been reduced, whereas psychosocial stress, caused by a very high work pace, competition and efficiency, and successive readjustment to organizational changes, has increased. This can be seen as part of a general and accelerating trend in modern society toward a more rapid pace of life, more frequent introduction of new technology, and continuous demands for coping with new conditions. Major improvements in physical conditions at work during the past decades have thus contributed to a switch in health focus, specifically to the role of psychosocial factors such as stress.

Developments in communication technology (faxes, e-mail, Internet, mobile phones, etc.) have enabled greater flexibility and mobility (e.g., teleworking) and have removed traditional boundaries between different roles in life (work, family, leisure). In addition, temporary employment and work on short-term

projects have become more common. These new trends are likely to involve the potential for beneficial effects in terms of greater variation and flexibility, but also an increased risk of stress due to work overload, role conflicts, and lack of time for rest and recovery. The individual, rather than the company, has to set the boundaries between work and his or her other roles in life.

Impact of the Work Environment

Conditions at the workplace may influence the individual in different ways. Physical conditions, such as noise, light, cold, heat, and so on are sensorily mediated by the individual and directly perceived as, for example, harmful or pleasant. In contrast, the individual cannot directly perceive exposure to many other physical conditions, such as radiation, certain chemicals and heavy metals, air and water pollution, and radioactive fallout, as harmful. The health risks associated with such work conditions are mainly based on information obtained from education, mass media, personal communication, or earlier experiences. In such cases, it is not often clear to what extent the stress and health problems associated with these occupational hazards are caused by the actual exposure or by the individual's own fear and anxiety from having been exposed.

Health problems can be caused by the effects of stress on various bodily systems, functions, and organs, such as blood pressure, secretion of stress hormones, immune functions, metabolism, the heart, the brain, and the gastrointestinal system. Health risks can also be caused by the effects of stress on various health-related behaviors, such as cigarette smoking, alcohol and drug abuse, poor eating habits, and lack of physical activity. Additional health risks at work are associated with violence or accidents caused by the greater risk of making mistakes under stress, or being reluctant (or neglecting) to use protective means (e.g., seat belts, helmets, hearing protection) when under time pressure.

Associations between work stress and cardiovascular illness (e.g., hypertension, myocardial infarction) have been reported repeatedly for a long time. However, there is also increasing evidence for strong associations between psychosocial work conditions and a great number of other health problems. A major work-related health problem today is that of musculoskeletal disorders. Neck, shoulder, and lower back pain are the most common reasons for absenteeism from work and for early retirement in Europe and North America, and also affect younger workers. In addition to the pain and suffering caused by these disorders, the economic costs are enormous.

Epidemiological studies have demonstrated dramatic and very consistent relationships between socioeconomic status and health. Social status is usually defined by type of occupation and educational level, and higher status is consistently linked to better health. The social gradient in health can only partly be explained by differential exposure to physical hazards at work, poor material conditions (food, housing), genetic factors, or health-related behaviors. Other factors must also be involved, and there is strong evidence that psychosocial factors at work and income inequality are important for the social differences in health.

Models of Work Stress

Several models have been proposed to explain the causes of work-related stress. Frankenhaeuser and colleagues and other investigators have described a model in which stress is defined in terms of the imbalance between the perceived demands from the environment and the individual's perceived resources to meet those demands. This imbalance can be caused by quantitative overload (a very high pace of work, too much work to do, etc.) or qualitative overload (too much responsibility, problems too complex to solve, conflicts, etc.). However, an interesting feature of this model is that it also proposes that stress may be due to an imbalance caused by understimulation, for example, by work tasks that are too simple, that do not allow individuals to use their education, skills, and experiences, and that do not allow them to learn new skills and develop their abilities. This situation can be found in monotonous and repetitive work, such as traditional assembly line work and in data entry work at video display units, and among people who are unemployed. It is also common among highly educated immigrants, who often have to accept very simple jobs due to insufficient knowledge of the new language or discrimination, which means that their training and experience cannot be used.

Another well-known model describing work stress or strain is the demand-control model, proposed by Karasek and Theorell and developed and expanded by others. According to this model, the combination of high demands and lack of control and influence (low job discretion) over the work situation causes high work strain. High demands combined with a high degree of control, which characterizes many high-status jobs, are described as an active work situation and are not associated with enhanced health risks.

The demand-control model has been tested in numerous studies that, in general, show that occupations characterized by high job strain, for instance, a

waiter or an assembly worker, are associated with elevated health risks compared with low-strain jobs, such as being a forester or a scientist. Although most studies are cross-sectional, thus excluding the possibility of making causal inferences, the few prospective studies that have been performed report similar findings. In the late 1980s, a third dimension – social support – was added to the demand-control model. High job strain combined with low social support at work contributes to even more elevated health risks.

The control dimension describes a wide range of factors typical of a positive and healthy work situation. It involves the individual's possibilities for developing and using his or her skills, knowledge, education, and experience to be able to work out new methods and ways of doing the job, learning new skills, taking responsibility, being independent, and experiencing variation at work. Low scores on this dimension have consistently been linked to various negative health outcomes, whereas the results regarding the dimension demands are less conclusive. A possible explanation for the inconsistent findings regarding high demands could be that this dimension does not distinguish between physical and mental demands or between quantitative (e.g., high work pace) and qualitative demands (e.g., too much responsibility). For example, individuals in high-ranking positions often report both high demands and good health.

Social support is generally considered to protect against stress at work or to serve as a buffer against health risks under stressful conditions. It is defined by factors such as having close social ties and someone to share emotional experiences with, good collaboration with colleagues and superiors, the possibility of getting help when needed, and adequate feedback about one's effort and performance. The number of social contacts is less important than the quality of these relationships. In a literature review, low social support was consistently found to be associated with higher morbidity and mortality.

Siegrist proposed a new model for stress at work called the effort-reward imbalance model. According to this model, lack of adequate reward in response to the individual's achievement efforts is considered to contribute to high stress levels and elevated health risks. Reward could be obtained in terms of economic benefits such as a higher income, but also in terms of appreciation and adequate support from colleagues and superiors, or by obtaining better career chances and a higher social rank at the job. A personality characteristic, overachievement, is also an important part of this model; individuals high in overachievement are at particular risk for health problems. In a

recent prospective study, this model was found to significantly predict elevated risk of myocardial infarction.

Type A Behavior

A stress- and work-related behavior pattern termed type A behavior has attracted a considerable amount of attention over the past decades. This attention was based, to a large extent, on findings from the prospective Western Collaborative Group Study, in which about 3000 middle-aged employed men were classified either as type A individuals or as their more relaxed type B counterparts on the basis of a standardized interview technique (the structured interview). At the 8.5-year follow-up, it was found that the prevalence of myocardial infarction was about twice as high among type A as among type B individuals, after controlling for traditional risk factors (blood pressure, blood lipids, cigarette smoking, etc.). This study initiated a great number of investigations and experiments aimed at revealing factors that contribute to the development of this behavior pattern and the psychophysiological mechanisms that could create a link to myocardial infarction. Work-related stress was found to play an important role in this context.

Type A behavior is defined in terms of an extreme sense of time urgency, impatience, competitiveness, and aggression/hostility. Work conditions in industrialized countries, emphasizing the importance of efficiency, productivity, a high work pace, and competitiveness, are considered to contribute to the development of this behavior pattern. In addition, individuals classified as type A have been found to be particularly responsive to challenges at work (obstacles to keeping up the pace of work, lack of control, competition, harassment, etc.) in terms of blood pressure, heart rate, blood lipids, and catecholamine output. Intensive, frequent, and/or sustained activation of these physiological stress responses contributes to the atherosclerotic process and to blood clotting and are, thus, likely to form a pathway between type A behavior and the elevated risk of myocardial infarction. Results for women are in general less consistent than they are for men, which could be explained by the fact that the structured interview was developed using male subjects.

The high work pace and competitiveness associated with the type A behavior pattern are usually reinforced at work by giving the individual a higher income, appreciation, and a successful occupational career (higher rank). Consequently, efforts to modify this behavior pattern in healthy individuals have not been particularly successful. However, after a

myocardial infarction individuals tend to be more motivated to change their lifestyle, and, indeed, a prospective intervention study has shown a reduced risk of reinfarction among individuals who were able to modify their type A behavior.

Interest in the global type A behavior has diminished in favor of one specific component of this behavior pattern – the aggression-hostility component, which seems to be the most toxic factor in terms of myocardial risk. The important role played by hostility in cardiovascular disease was first demonstrated in a longitudinal study by Barefoot and colleagues, which found that medical students with high scores on the Cook-Medley hostility scale of the Minnesota Multiphasic Personality Inventory (MMPI) had a six-fold increase in mortality when followed up 25 years later, mainly due to coronary heart disease (CHD). Subsequent studies have consistently supported this finding by showing that individuals who are high in hostility have a significantly increased risk of myocardial infarction. As medication to prevent and treat cardiovascular disease has improved considerably during the past decades and the incidence rate of myocardial infarction has declined steadily since 1980, interest in performing large prospective studies on type A behavior and CHD has diminished accordingly.

Gender Differences in Response to Work Stress

As the number of women in the labor force approaches that of men but the traditional female responsibility for home and family mainly remains the same, stress from work overload and role conflicts has become an increasing problem for many women. Although women generally live longer than men, women tend to report more health problems than men. Women's longevity is associated with behavioral factors (e.g., men use more drugs and alcohol, men commit suicide more often, men expose themselves to greater risks at work and in traffic), environmental factors (men perform more dangerous jobs, are more violent, and engage in criminal behavior more often) and biological factors (women contract fatal cardiovascular disorders such as myocardial infarction and stroke about 10 years later in life than men, mainly due to the protective effects of female sex hormones before menopause). However, musculoskeletal and gastrointestinal disorders, headache, chronic fatigue, and psychiatric disorders are reported more frequently by women than by men.

Women's employment, even in low-status jobs, seems to be associated with better health compared to the role of a homemaker. To some extent this could

be explained by the fact that it is easier for women in good health to get and keep a job, compared with women with poorer health. However, a paid job is also likely to contribute to better health and well-being by increasing the possibilities for social relations, higher self-esteem, and economic independence. Provided that men and women are matched for education and occupational level, physiological stress responses at work seem to be quite similar. However, consistent gender differences have been found off the job. Frankenhaeuser and colleagues compared stress responses during and after work in male and female white collar workers, matched for age and occupational level, and found that men's physiological arousal rapidly returned to baseline after work, whereas women's stress levels remained high several hours after work. These findings have been replicated in recent studies of men and women in high-ranking positions. A likely explanation for these gender differences is that women were unable to unwind and relax due to their greater responsibility for unpaid work at home (e.g., household chores, child care).

Several studies show that women's work stress is reflected not only at work but also in terms of their physiological arousal in non-work conditions. Men seem to respond more specifically to the acute stress exposure at work, and their work stress does not seem to spill over into non-work conditions.

In a prospective study of approximately 600 000 men and 400 000 women in Sweden, Alfredsson and colleagues found that overtime at work (10 h or more per week) was associated with a significantly elevated risk of myocardial infarction during a 1-year follow-up in women but not in men. Men's overtime was even associated with a significantly reduced risk of infarction.

One possible explanation for this gender difference, which is supported by psychophysiological data in other studies, is that women's CHD risk is related to elevated and sustained physiological stress levels caused by work overload and their more pronounced role conflicts, when they are trying to combine overtime at work with responsibility for various unpaid duties at home. Another possible explanation is that women, more often than men, are employed in low-status jobs, in which high demands are combined with little influence over the work situation, including overtime. Such high-strain jobs, according to the demand-control model, are known to increase the risk of CHD in both men and women.

A paid job as well as the unpaid work of household chores and child care is likely to contribute to the greater total workload of full-time employed women, compared with men. This could be relevant for women's greater health problems, but it also

reduces their chances of having a professional career on the same terms as men. A study of about 1000 male and 1000 female full-time employed white collar workers, matched for age and type of occupation, confirmed that a greater proportion of women compared to men reported having the main responsibility for most unpaid duties at home. In terms of number of working hours in paid and unpaid productive activity, the total workload of men and women seems to be about the same in families having no children at home, whereas the workload increases more rapidly for women than for men depending on the number of children at home.

Psychobiological Mechanisms Linking Work Stress to Health Problems

Allostatic Load

A new stress model, the allostatic load model, refers to the ability to achieve stability through change. A normal and economic response to stress means activation of physiological systems in order to cope with the stressor, followed by a shut-off of the allostatic response as soon as the stress is terminated, whereas over- or underactivity of the allostatic systems may add to the wear and tear of the organism. Examples are frequent and intensive activation of physiological systems (cardiovascular, hormonal, metabolic, immune function) without enough time for rest and recovery or an inability to shut off the stress response after the stress exposure, which may cause overactivity and exhaustion of the systems. Overexposure to stress hormones increases the risk of cardiovascular illness and immune deficiency, as well as cognitive impairment. Lack of adequate response in one system, due to exhaustion, may cause compensatory overactivation of other systems.

The allostatic load associated with blue collar jobs is usually higher than that associated with white collar jobs. Manual jobs involve mental as well as physical stress and are associated with more pronounced physiological responses. In addition, repetitive work associated with many blue collar jobs seems to contribute to sustained levels of stress after work, which further adds to the allostatic load. In women, the unpaid work responsibilities of household chores and child care may further contribute to a lack of opportunity for unwinding and to sustained stress levels in non-work situations.

Health problems are consistently more common among blue collar workers with low education, responsibility for monotonous and repetitive tasks, and low income than among white collar workers with more stimulation and variation at work.

Work Stress and Activity of the Hypothalamic-Pituitary-Adrenocortical Axis

Negative psychosocial and socioeconomic factors are associated not only with increased morbidity and mortality but also with elevated activity of the hypothalamic-pituitary-adrenocortical (HPA) system and increased cortisol secretion. Additionally, a very high workload, such as regularly working more than 10 h of overtime per week, has been associated with markedly elevated cortisol levels, at least in women. Sustained activity of the HPA system is related to a series of endocrine and metabolic effects, causing, among other things, increased storage of fat in the abdominal region. The amount of central fat accumulation indicates long-term overactivity of the HPA system and can be measured as the relationship between the waist and the hip circumference, the waist-hip ratio (WHR). An association has been demonstrated between high WHR and a series of negative socioeconomic factors, such as low education and income, poor housing and/or living alone, psychiatric problems and use of antidepressive drugs, and high absenteeism from work. The relationship between low socioeconomic status and high WHR is enhanced by the fact that health-related behaviors, such as cigarette smoking, alcohol and drug abuse, and lack of exercise, also contribute to increasing the activity of the HPA system. High WHR has been shown to increase the risk of diabetes and cardiovascular disease, and, through its anti-inflammatory effects, cortisol also has an important role in the functioning of the immune system. It has been concluded that chronic or long-term stress is associated with compromised immune functions and, thus, increased risk for infections and slower healing of wounds. Elevated cortisol levels have recently also been related to cognitive functions, such as explicit memory deficiency and low hippocampal volume.

Thus, in summary, the pattern of results suggests that individuals exposed to negative psychosocial work conditions (low income, low education, risk of unemployment, etc.) are more likely to have elevated cortisol secretion, more central fat accumulation, and greater health risks.

Work Stress and Musculoskeletal Disorders

Musculoskeletal disorders increased dramatically during the 1980s and have become one of the most important work-related health problems in Europe and North America today. Research indicates that psychosocial work stress is an important factor contributing to this development.

The association between such factors as bad ergonomic conditions at work, heavy lifting, and physically

monotonous or repetitive work and an increase in shoulder, neck, and lower back pain problems has been well documented. However, considerable ergonomic improvements of the work environment have not resulted in a lower incidence of musculoskeletal disorders, and musculoskeletal disorders are frequent not only in physically demanding jobs but also in light physical work. An increasing number of studies report an association between psychosocial factors at the workplace and neck, shoulder, and lower back pain problems. Conditions typical of many low-status jobs, such as low work satisfaction, time pressure, lack of influence over one's work, and constant involvement in repetitive tasks of short duration, often characterize jobs associated with a high risk for muscular problems.

Musculoskeletal disorders differ from many other major health problems, such as cardiovascular disease and cancer, in that symptoms often appear very early in life and after a relatively short exposure to adverse environmental conditions. In repetitive work, pain syndromes are often reported after only 6–12 months on the job, and it has been documented that even very low levels of muscle activation (less than 1% of maximal voluntary contraction) may contribute to the development of chronic pain syndromes.

So far it has been difficult to explain the high incidence of musculoskeletal disorders in light physical work. However, it has been suggested that sustained low-level muscle activity, induced by physical and/or psychological demands, may initiate a pathogenetic mechanism resulting in muscle pain and thus form a link to musculoskeletal disorders. In a recent experimental study, it was demonstrated that the smallest functional units of the muscle, the motor units, can be activated by physical as well as mental stress. Psychological and psychosocial factors on and off the job, muscle pain, and illness behavior may also form a vicious circle with increasing sensitization and pain symptoms. Eventually, the individual will become chronically ill.

An important feature of psychological stress, which could be relevant to its role in the etiology of muscle pain, is that it is more lasting or chronic than physical demands at work. Stressful conditions such as low job satisfaction, low income, low status, an irritating boss, and fear of losing one's job influence the individual more or less continuously, whereas physical demands terminate at the end of the workday and during breaks at work.

Support for the assumption that work stress contributes to muscle tension and pain has been obtained in several studies. For example, in an interesting prospective study of female packing workers, it was found that women who contracted clinically diagnosed

trapezius myalgia within the first year of employment had significantly higher muscle activity during breaks at work but not during actual work and, in addition, had fewer periods of very low muscular electrical activity (electromyographic [EMG] gaps). These findings indicate that, in the modern work environment, lack of relaxation during breaks at work and after work may be an even more important health problem than the actual level of stress or the intensity of muscle activation during work.

The prevalence of musculoskeletal disorders is markedly higher among women than among men. One would generally expect that this gender difference could be explained by women's lower physical capacity compared with men. However, because several studies show that the physical characteristics of the individual do not seem to predict future musculoskeletal disorders and that the physical load in white collar jobs, where the gender difference is most pronounced, is usually quite low, a more likely explanation is that women are often employed in stressful, emotionally demanding, monotonous, and repetitive jobs, where the risk of developing neck and shoulder disorders is high. Additional explanations could be that the physical work environment is better suited for men than for women, so that chairs and desks are too high for shorter women and tools are too big and heavy for women's smaller hands. Also the work organization is usually designed by men and may be less adequate for women. Lack of unwinding after work may further contribute to the higher health risks for women.

Concluding Remarks

Numerous studies suggest an important role not only for physical but also for psychosocial stress at work in major health problems, and several plausible psychobiological mechanisms have been proposed. Two important neuroendocrine stress systems – the sympathetic adrenal medullary and the HPA systems – seem to play an important role for these relationships.

Information on psychobiological pathways between psychosocial stress at work and symptoms and illness is of great importance for the possibility of preventing and treating work-related ill health. Such knowledge could also help individual workers to better understand their own health problems and find ways of breaking vicious circles that form between work stress, behavior, and symptoms. It may also help to create a more understanding attitude in general toward people who, under stressful work conditions, have developed somatic symptoms. However, most important is that knowledge about these

mechanisms is a strong incentive for implementing structural and organizational changes at work in order to protect people from mental and physical disorders. The psychobiological parameters may be used as warning signals but may also offer new possibilities for evaluating improvement of work conditions before they are reflected in somatic illness patterns, which usually (but not always) take a long time to develop. With regard to the enormous costs and suffering associated with musculoskeletal disorders, actions leading even to a moderate or small reduction of these problems would be extremely cost efficient.

The new forms of work that have become possible through the development of communication technology and that allow maximal flexibility and mobility have the potential for beneficial as well as harmful stress effects. The balance between negative and positive consequences of this type of boundaryless work is likely to be determined by factors such as the organization of work, the creation of new boundaries between different roles, and individual factors. An adequate balance between activation (energy mobilization) and rest and recovery (e.g., recreation, healing, growth) is necessary for long-term health.
